Epstein-Barr Virus-Associated γδ T-Cell Lymphoproliferative Disorder Associated With Hypomorphic IL2RG Mutation

Kay Tanita, Akihiro Hoshino, Ken-Ichi Imadome, Takahiro Kamiya, Kento Inoue, Tsubasa Okano, Tzu-wen Yeh, Masakatsu Yanagimachi, Akira Shiraishi, Masataka Ishimura, Tilmann Schober, Meino Rohlfis, Masatoshi Takagi, Kohsuke Imai, Hitotoshi Takada, Shouichi Ohga, Christoph Klein, Tomohiro Morio and Hirokazu Kanegane

Chronic active Epstein-Barr virus (EBV) infection (CAEBV) is an EBV-associated lymphoproliferative disease characterized by repeated or sustainable infectious mononucleosis (IM)-like symptoms. EBV is usually detected in B cells in patients who have IM or Burkitt’s lymphoma and even in patients with X-linked lymphoproliferative syndrome, which is confirmed to have vulnerability to EBV infection. In contrast, EBV infects T cells (CD4+ T, CD8+ T, and γδ T) or NK cells monol- or oligoclonally in CAEBV patients. It is known that the CAEBV phenotypes differ depending on which cells are infected with EBV. CAEBV is postulated to be associated with a genetic immunological abnormality, although its cause remains undefined. Here we describe a case of EBV-related γδT-cell proliferation with underlying hypomorphic IL2RG mutation. The immunological phenotype consisted of γδT-cell proliferation in the peripheral blood. A presence of EBV-infected B cells and γδT cells mimicked γδT-cell-type CAEBV. Although the patient had normal expression of CD132 (common γ chain), the phosphorylation of STAT was partially defective, indicating impaired activation of the downstream signal of the JAK/STAT pathway. Although the patient was not diagnosed as having CAEBV, this observation shows that CAEBV might be associated with immunological abnormality.

Keywords: chronic active Epstein-Barr virus infection, γδT-cell, common γ chain, IL2RG, JAK/STAT pathway

INTRODUCTION

Epstein-Barr virus (EBV) infection is a very common disease that is found in >90% of all adults with a lifelong occurrence. EBV infections commonly occur asymptptomatically in infants and young children, but some individuals present infectious mononucleosis (IM), which typically manifests as fever, pharyngitis with petechiae, exudative pharyngitis, lymphadenopathy, hepatosplenomegaly,
and atypical lymphocytosis. EBV is usually detected in B cells from patients who have IM or Burkitt’s lymphoma. Even in X-linked lymphoproliferative syndrome (XLP), which is a primary immunodeficiency disease (PID) characterized by vulnerability to EBV infection, B cells are similarly infected with EBV. On the other hand, in most patients with chronic active EBV infection (CAEBV), which is characterized by repeated or sustained IM-like symptoms, the virus is detected in T cells (mainly in CD4+ T cells, and less in CD8+ T cells and γδ T cells) or NK cells (1, 2). Hypersensitivity to mosquito bites and elevated levels of serum IgE are observed in patients with NK cell-type CAEBV (3). In contrast, in Europe and the United States, which are known to have fewer cases than Asian countries, CAEBV patients are likely to show B-cell-type infection, B-cell depletion and hypogammaglobulinemia (4). This is suggested to be due to differences in the genetic background or environmental factors, and the pathological condition may differ depending on such differences in those infected with EBV; however, the pathophysiology of this condition remains unclear.

Severe combined immunodeficiency (SCID) is a severe form of PIDs, and is defined as a combined functional disorder of both T cells and B cells, which finally results in cell-mediated and humoral immunodeficiency (5). X-linked SCID, which is a common γ chain (γc) deficiency, is the most common phenotype. As next-generation sequencing (NGS) becomes a more common diagnostic tool, the numbers of inherited immune defects might rise even further. Immunodeficiency and autoinflammatory diseases might be found to be atypical phenotypes of SCID caused by hypomorphic IL2RG mutation. Here, we report on a Japanese adult with recurrent respiratory infection and EBV-associated leiomyoma during childhood, who developed recurrent infection in his adolescence. The patient was diagnosed having CAEBV-like EBV-associated γδT-cell lymphoproliferation, and was finally revealed to have IL2RG mutation.

RESULTS
Case Presentation
The patient was a 21-years-old Japanese male with no family history suggestive of immunodeficiency. He was born to non-consanguineous Japanese parents. He had experienced recurrent respiratory infections since childhood. At the age of 6 years, he was hospitalized with EBV-associated leiomyoma in his right bronchus, and complement deficiency (C2 and C9), low T-cell count, and reduced responses to phytohemagglutinin (PHA) and concanavalin A (ConA) were also found (6). PID of unknown cause was suspected and Trimethoprim-Sulfamethoxazole (TMP-SMX) was started. He developed Yersinia enteritis at the age of 8 and pleurisy at the age of 9. After that, he did not experience severe infection for 10 years, even after discontinuing TMP-SMX at the age of 12. Chronic cough, purpura, edema, and pain of the lower limbs appeared at the age of 19. A skin biopsy was performed, which led to a diagnosis of leukocytic fragmentative vasculitis; however, immunosuppressive therapy was postponed due to his past medical history of immunodeficiency. At the age of 21, he was hospitalized with invasive Haemophilus influenzae infection, which had been stabilized following adequate antimicrobial therapy, and he also suffered from recurrent pneumonia caused by multiple pathogens. Extensive immunological evaluations showed dysgammaglobulinemia, with reduced IgG (608 mg/L) and IgG2 (109 mg/dL), elevated IgA (692 mg/dL), normal IgM (62 mg/dL), reduced IgE (<3 IU/mL), and reduced CH50 levels (16 U/mL) (Supplementary Table 1), along with reduced lymphocyte proliferation (PHA 6,700 cpm and ConA 4,460 cpm). Lymphocyte subpopulation analysis showed reduced T cells, a paucity of B cells, and an increase of NK cells (Table 1). In CD3+ T cells, a markedly increased number of γδT cells was observed, and T cells were skewed to the memory phenotype, especially central memory T cells. The kappa-deleting recombination excision circles level was low but detectable, while the T-cell receptor excision circles level was undetectable. The patient exhibited normal production of specific antibodies against varicella zoster virus (VZV), mumps, rubella, and measles.

Virological Examination
Virus DNA quantitative tests revealed the presence of EBV in peripheral blood mononuclear cells (PBMCs) and plasma (9.0 × 10^2 copies/μgDNA and 4.3 × 10^5 copies/mL, respectively), and cytomegalovirus (CMV) was also detected in plasma (4.5 × 10^3 copies/mL). EBV was detected not only in CD19+ B cells (2.1 × 10^4 copies/μgDNA) but also in γδT cells (2.1 × 10^5 copies/μgDNA). Interestingly, RT-PCR analysis demonstrated that EBV in B cells was positive for EBNA1, EBNA2, LMP1, LMP2A, and LMP2B transcripts, whereas EBV in γδT cells was positive for EBNA1, LMP1, and LMP2A, but negative for EBNA2 and LMP2B transcripts. These findings indicated that EBV in B cells showed latency III infection; however, EBV in γδT cells showed latency II. Chronological data of EBV-related antibodies were shown in Supplementary Table 2.

Genetic Findings
Whole-exome sequencing (WES) identified a hemizygous mutation in IL2RG c.982C>T (p. R328∗) in the patient. This mutation was confirmed by Sanger sequencing (Figure 1A). The mother was the heterozygous carrier of this variant. WES also revealed a homozygous mutation in C9 c.346C>T (p. R116∗), indicating the cause of his complement deficiency.

Immunological Findings
The mutation was present in exon 8 of IL2RG, which corresponds to the intracellular domain of the γc chain (Figure 1B). Flow cytometric examination using an antibody recognizing the extracellular domain of the CD132 molecule was positive (Figure 1C). However, the phosphorylation of STAT3, STAT5, and STAT6 after cytokine stimulation was partially defective (Figure 1D). In the patient, proliferative capacity was slightly decreased in both CD4+ and CD8+ T cells, and markedly decreased in CD4−CD8− cells which correspond to γδT cells (Figures 2A, B). The function of NK cells was normal as revealed by assessing the expression of CD107a (Figure 2C). EBV-specific CD8+ T cells were detectable as well as CMV-specific CD8+ T cells (Supplementary Figure 1). Southern blot analysis of
TABLE 1 | Lymphocytes profile of the patient at 21 years of age.

| Lymphocyte profile | % (μL) | Reference value in adults |

Clonotypes (Figure 2E). These findings indicated that expanded EBV-infected γδT cells might have impaired immunological function and play a pivotal role in the pathogenesis of the disease.

**Clinical Course After Diagnosis and Immunological Examination**

A few months after the diagnosis, the patient presented with high fever, whole body rash with small blisters, and EBV (6.8 × 10^3 copies/μgDNA) and VZV (1.7 × 10^4 copies/μgDNA) viremia. The symptoms disappeared after the initiation of oral valacyclovir (VACV) for 5 days, but EBV and VZV were persistently positive in blood. Three weeks after the VACV treatment, the patient was admitted to hospital with the symptoms of high fever, cough, abdominal pain, and purpura, edema, and pain of the lower limbs. Intravenous antibiotic, acyclovir, and intravenous immunoglobulin treatment were not effective. Rituximab was also used to diminish the EBV infection in B cells, but it did not help to resolve the clinical symptoms. CMV and HHV-7 became positive along with EBV and VZV a week after admission, and the antiviral drug was switched to ganciclovir. Methylprednisolone pulse (15 mg/kg/day × 3 days) treatment was performed against hypercytokinemia [neopterin: 52 nmol/L (<5), IL-18: 3,260 pg/mL (<500), IL-6: 104 pg/mL (<5), sTNF-R1: 2,020 pg/mL (484–1,407), and sTNF-RII: 5,800 pg/mL (829–2,262)]. These treatments successfully resolved the symptoms and all four viruses became negative.

At the age of 21, the patient underwent a bone marrow transplantation from an HLA-matched unrelated donor (total nucleated cell dose 3.2 × 10^9 cells/kg) with fludarabine at 180 mg/m^2, melphalan at 140 mg/m^2, etoposide at 450 mg/m^2, and 3 Gy of total body irradiation. Graft vs. host disease (GvHD) prophylaxis with tacrolimus and short-term methotrexate were given. Although the patient achieved prompt neutrophil engraftment on day +17, acute GvHD (Grade 1: skin 2, liver 0, gut 0) developed. Additional therapy with prednisolone controlled the GvHD. Complete donor chimerism of PBMCs was demonstrated at day +21 and that of bone marrow mononuclear cells at day +29. EBV could not be detected from γδT cells, other types of T cells, B cells, NK cells, or blood plasma at day +85.

**DISCUSSION**

The protein encoded by IL2RG is an important signaling component of many cytokine receptors, including those of IL-1, −4, −7, −9, −15, and −21, and is thus referred to as γc (7). Mutations in IL2RG cause signal abnormality of these cytokines and the development of T−B−NK− SCID. In the present case, although numbers of T cells and NK cells were relatively well-maintained, most of the T cells were γδ T cells lacking much of an ability to proliferate. Immunological assessment showed that phosphorylation of STAT3, STAT5, and STAT6 was partially reduced but not completely diminished. These findings suggested that this mutation (p. R328*) was hypomorphic.

The patient was also associated with C2 an C9 deficiency, and homozygous nonsense mutation in the C9 was identified. C9 deficiency is the most common complement deficiency in

Japan, but is very rare in western countries. The incidence of C9 deficiency was estimated to be 0.086–0.12% in Japan (8–10). Autoimmune, renal and infectious diseases were observed in some patients with C9 deficiency. The patient suffered from leukocytic fragmentative vasculitis, which might be associated with C9 deficiency.
The EBV latent infection type is classified into four types depending on the EBV genes expressed: latency I, latency II, latency III, and latency 0. Latency I is seen in Burkitt's lymphoma or nasopharyngeal carcinoma, latency II in Hodgkin lymphoma or nasal NK/T lymphoma, and latency III in opportunistic lymphoma with HIV infection and PIDs. In CAEBV, EBV infection shows latency II (11). Latency II infection in γδ T cells might be compatible with CAEBV and other malignancies, and latency III infection in B cells might be compatible with PIDs.

The patient had EBV-associated leiomyoma at the age of 6 (6). EBV-positive smooth muscle tumor (SMT) is an extremely rare entity, and it is observed in patients infected with human immunodeficiency virus or undergoing immunosuppressive treatment after organ transplantation. In addition, SMT is observed in pediatric patients with PIDs including SCID (12). Recombinase activating gene (RAG)1 and RAG2 are involved in V(D)J recombination of immunoglobulin and T-cell receptor (13). Patients with complete loss-of-function mutations of RAG1/2 genes show complete lack of T and B cells (T^-B^-NK^- SCID). On the other hand, in patients with remaining activity of RAG1/2 caused by hypomorphic mutation, B and T cells are somewhat differentiated, although they lose their diversity. This leads to the failure of immune tolerance, abnormal proliferation and activation, cytokine production biased toward Th2, and inappropriate IgE production by B-cell clones. Patients who have these conditions present with Omenn syndrome at birth (Figure 3, left panel). Patients with less hypomorphic RAG1/2 deficiency were reported to have CMV infection and γδT-cell proliferation (14, 15). In addition to the instability of immunity due to genetic abnormalities, environmental factors, such as viral infection might lead to γδT-cell proliferation. Likewise, patients with hypomorphic IL2RG mutation also present with an Omenn-like phenotype, while complete loss-of-function mutation in the IL2RG gene is linked to X-linked SCID (T^-B^-NK^- SCID) (Figure 3, right panel). Partial activity of the IL2RG gene makes the immunity fragile and may facilitate the infection of herpesviridae viruses, such as CMV and EBV and may feature a characteristic pathological condition of γδT-cell proliferation as well as in the case of hypomorphic RAG1/2 deficiency with CMV infection and γδT-cell proliferation. Recently, the same mutation was noted in another patient with SCID; however, the phenotypic data for that case were not reported (16). Accordingly, this is the first description of the effect of this IL2RG mutation.

CONCLUDING REMARKS

The patient developed EBV-associated γδ T-cell lymphoproliferative disorder, which is virologically similar with γδ T-cell type CAEBV. The patient also presented atypical γc deficiency with hypomorphic IL2RG mutation. Although the diagnosis of CAEBV is made without underlying diseases including PIDs, the disease is supposed to be associated with immunological deficit. A few cases of CAEBV is associated with PRF1 and STXBP2 mutations (17, 18). Although the pathology of CAEBV remains unknown, the experience of this case suggests that immune abnormality is deeply involved in its onset. The
accumulation of such cases should promote our understanding of the pathophysiology of CAEBV and related illness.
