We present evidence that the metal-insulator transition (MIT) in a tensile strained NdNiO$_3$ (NNO) film is facilitated by a redistribution of electronic density and neither requires Ni charge disproportionation nor symmetry change [1, 2]. Given epitaxial tensile strain in thin NNO films induces preferential occupancy of the e$_g$ $d_{z^2}$ orbital ($d_{x^2-r^2}$) we propose the larger transfer integral of this orbital state with the O 2$p$ mediates a redistribution of electronic density from the Ni atom. A decrease in Ni $d_{z^2-r^2}$ orbital occupation is directly observed by resonant inelastic x-ray scattering below the MIT temperature. Furthermore, an increase in Nd charge occupancy is measured by x-ray absorption at the Nd L$_3$ edge. Both spin-orbit coupling and crystal field effects combine to break the degeneracy of the Nd 5$d$ states shifting the energy of the Nd e$_g$ $d_{z^2-r^2}$ orbit towards the Fermi level allowing the A site to become an active acceptor during the MIT transition. This work identifies the relocation of electrons from the Ni 3$d$ to the Nd 5$d$ orbitals across the MIT. We propose the insulating gap opens between the Ni 3$d$ and O 2$p$ resulting from Ni 3$d$ electron localization mediated by charge loss. The transition seems neither purely Mott-Hubbard nor simple charge transfer.

Introduction

The discovery of superconductivity sparked interest in emergent phenomena in correlated electron materials, including metal insulator transitions [3]. Many different models including the Mott-Hubbard, Mott-Heisenberg, charge-transfer, covalent insulator and Slater insulator have been suggested to explain the phenomena of a MIT in a material with partially filled d-bands. The proximate cause of a transition in a particular material, however, can be difficult to determine due to the delicate balance of forces experienced by the electrons, including intra-electron, spin-spin, spin-orbital and electron-lattice interactions. Epitaxial growth offers the opportunity to test different MIT theories as strain modifies the interatomic distances of chemically identical compounds and can thus isolate interactions that drive the MIT [4].

Temperature driven MIT in NdNiO$_3$ (NNO) occurs at ~200K. Many different electronic and structural rearrangements accompany this transition. Antiferromagnetic order [5]; structural changes, including an increase of orthorhombic rotations in concert with a small volume increase [6]; Ni charge disproportionation and redistribution mediated by oxygen have been reported in bulk samples [1].

Interpretation of the MIT phenomenon centers upon whether the transition falls under a Mott-Hubbard [9, 10] or charge transfer paradigm [11]. In a Mott-Hubbard phase transition the repulsive Coulomb force between electrons (U) causes the electrons to localize opening a band gap between the occupied and unoccupied d electron states of the transition metal. In the charge transfer mechanism the band gap opens between the transition metal d states and the oxygen 2$p$ orbitals. In addition Stewart et al. proposed that the insulating gap is not closed by evolving changes in the Ni or O states immediately above and below the gap, but rather by the emergence or activation of electronic states in the insulating gap [12]. Yamamoto and Fujiwara calculated that the details of the Ni-O bond with AFM ordering in bulk NNO find a gap opening [13], in reasonable agreement with the measured insulating gap [14].

This work demonstrates that charge order is not requisite for the MIT and eliminates models based upon this phenomenon. Additionally, we propose a subtle charge redistribution process occurs coincident with the MIT. In tensile strained thin NNO films grown on SrTiO$_3$ (001) we found neither, evidence of charge disproportionation, symmetry change, nor an increase of octahedral rotations across the MIT transition. However a charge-relocation from the Ni to the Nd atom is seemingly observed across the transition. We propose a partial B-site charge transfer to the A-site 5$d$ state.

Furthermore, the migration of charge from the Ni in the insulating state combined with a lattice expansion suggests the remaining Ni d electrons will be increasingly localized, contributing to the opening of an insulating gap.

Experimental Results.
Recent transport measurements demonstrated that tensile strain in NNO preserves the MIT, while compressive strain extinguishes the insulating phase [15]. Two epitaxial NNO films, prepared by PLD [15], are studied in this work. The first is 10 unit cells grown on LaAlO$_3$ (001) (LAO) in an almost unstrained state (0.3% compressive), shows no MIT or temperature dependent structural change. The second sample is a fully strained, 30 unit cell film grown on SrTiO$_3$ (001) (STO), in a tensile strain state (2.6%). The NNO/STO MIT temperature is reduced from the bulk value to ~180 K [15]. Both films are fully strained to their respective substrates while the out-of-plane lattice parameters are 3.84 Å and 3.75 Å on LAO and STO respectively [15]. Structural changes in both films are measured with x-ray diffraction while electronic changes are measured with resonant x-ray diffraction, x-ray absorption spectroscopy (XAS) and resonant inelastic x-ray scattering (RIXS). All experiments were performed at the Advanced Photon Source, Argonne National Laboratory.

Specular rod (L) scans through (0 0 2) reflections from both samples are shown in Fig. 1a. In the tensile strained film, the orthorhombic c-axis lies along all three a, b and c crystallographic directions of the STO substrate, while, for the LAO substrate, it is confined to the substrate plane (Fig. 1b, d). In NNO/STO the out-of-plane lattice constant of the film undergoes thermal contraction with decreasing temperature and shows no transitional expansion. In the case of NNO/STO the out-of-plane lattice constant of the film increases coincident with the MIT. Bulk NNO also exhibits a volume expansion (primarily derived from the orthorhombic b direction), similar in magnitude to what is observed in the NNO/STO film [6]. The (1/2 1/2 5/2) diffraction peak from NNO/STO, which constitutes primarily...
octahedral rotations, is presented in Fig. 2b. There is no evidence of a significant intensity change as the sample passes through the MIT or as the incident energy is tuned through the Ni K-edge. This indicates that, unlike bulk NNO, no charge order emerges below the transition temperature. Subsequent measurements on single domain NNO found the same result [16]. Previous Ni K resonant diffraction interpreted their results as evidence of emergent charge order resulting from a Ni charge disproportionation and posited that it drove the MIT [1]. Density functional calculations have however suggested that such charge disproportionation is not necessary for the MIT in LuNiO$_3$ [9].

has been determined, however, that it is energetically favorable to transfer partial hole from the Ni to the hybridized Ni-O bond. Thus, the ground state is generally described as mixture of $|3d^72p^6\rangle$ and $|3d^6L\rangle$, where $L$ is the ligand hole [17, 18, 19]. In the electronic state $|3d^6L\rangle$ a hole is donated from the O 2$p$ states to the Ni 3$d$ states. The latter, however, may be hybridized with the O 2$p$ and thus can be better understood as Ni 3$d$ with some O 2$p$ character [20]. The $L$ consists of $p\sigma$ or $p\sigma_v$ orbitals [21]. An increase in the pre-edge peak intensity may be interpreted as a decrease in the Ni $e_g$ occupation. Thus the metallic phase has greater Ni $e_g$ occupation than the insulating phase. Naively it might be assumed that the electrons are exchanged with the O ions. XAS measurements of NNO at the O edge, however, do not show any measurable change through the transition temperature [18], suggesting that this is not the case.

To complete the picture of the electronic configuration, XAS measurements at the Nd L$_3$ edge were performed, Fig. 3b. A significant response of the white line was measured from the NNO/STO sample as a function of incident x-ray polarization. The degenerate 5$d$ states of the Nd ion are split by a combination of spin-orbit coupling and crystal field, as illustrated in the inset. For rare earths, the strong spin-orbit coupling from the 4$f$ orbital influences the 5$d$ states via the 4$f$-5$d$ exchange interaction [22]. As a result, the $J_{5/2}$ state is driven towards the Fermi energy, becoming potentially active. Therefore, at the L$_3$ edge, the XAS spectra show polarization dependence for the incident x-ray while no difference is observed at the L$_2$ edge (not shown).

The XAS measurements at the Nd L$_3$ edge also reveal a small change above and below the transition temperature. This is unexpected because the A site is not, in the literature, typically ascribed a role in the MIT. When cooled below the transition temperature, the white line intensity decreases in the out-of-plane (E//c) measurement, which is indicative of an increase of the electron occupation for the Nd 5$d$ state. Combined with the observed reduction of the Ni 3$d$ occupation these results suggest a partial electron transfer from the Ni 3$d$ to the Nd 5$d$ across the MIT.

Electron transfer from Ni to Nd naively seems unlikely because a large energy separation is typically calculated between A and B site electrons in transition metal oxides. Experimentally, however, there is clear evidence of Ni-Nd interaction. Femtosecond resonant soft x-ray diffraction with high-resolution spectroscopic analysis has shown the

Temperature dependent XAS spectra at the Ni K edge from NNO/STO are shown in Fig. 3a. Below the transition temperature there is an increase in the intensity of the Ni K pre-edge peak. The pre-edge peak results from a 1$s$ to 3$d$ ($e_g$) transition. Nominally, the Ni electronic configuration is Ni 3$d^7$. It
low-temperature magnetic dynamics of the Ni and Nd lattices are coupled [23]. Indeed, a second set of resonant soft x-ray diffraction measurements have shown that the Nd magnetic order is induced by the Ni magnetic order [24]. Furthermore, in the case of another rare-earth-3d perovskite material, EuTiO3, direct A-B site hybridization has been measured [25] and calculated [26].

To explore the microscopic origins of Ni electron behavior resonant inelastic x-ray spectroscopy (RIXS) measurements are performed at the Ni K pre-edge. RIXS spectra from NNO/STO at a variety of incident energies are shown in Fig. 4a. The energy loss of the peaks remains constant regardless of incident energy, indicating a true RIXS signal and the measurement at the pre-edge incident energies indicates a direct, as opposed to indirect, RIXS process at work.

While both low spin [18, 27, 6] and high spin [9] configurations have been presented in the literature this data is most consistent with a low spin configuration with an eg occupation less than 2 (>1). The experiments were performed at sector 9 at the APS using a spherical (1m radius) diced Ge(6 4 2) analyzer is used to obtain an overall energy resolution of 200 meV. To minimize the elastic background, most of the measurements were carried out in a horizontal scattering geometry. The Ni K pre-edge excites a 1s core electron to an empty 3d state, the excited system quickly decays: a d electron from below the Fermi level fills the 1s core hole and a photon is emitted. The energy difference between the emitted and incident photon is equivalent to the energy difference between an unoccupied and occupied d state, a dd excitation [28, 29].

The NNO/LAO RIXS spectrum, shown in Fig. 4d, shows one dd excitation, at 0.79 eV energy loss, which is identified as the energy difference between eg and t2g electron energies and is thus a measure of the crystal field splitting [12]. The RIXS spectrum from NNO/STO presents two peaks at 0.6 eV and 1.0 eV (Fig. 3d). The emergence of two dd transitions is attributed to strain-induced eg splitting while the one peak is observed in the 0.3% compressively strained film, where the expected eg splitting is beyond resolution. Strain imposes a tetragonal distortion on the unit cell, resulting in a modification of the Ni-O bond lengths in the NiO6 octahedra, as shown in the inset of Fig. 4c. This bond distortion reduces the crystal field symmetry and removes the two-fold eg orbital degeneracy. In the case of tensile strain the in-plane lattice expands, reducing the energy of the d_{x^2−y^2} orbital and conversely the out-of-plane d_{3z^2−r^2} orbital rises with the reduced c-axis lattice parameter.

The loss energies do not change through the volume expansion of the MIT indicating that the relative energies of the orbitals are constant within the resolution of the experiment. The lower energy intensity (d_{x^2−y^2}) however, increases in the insulating phase while the higher energy (d_{3z^2−r^2}) intensity remains unchanged (as illustrated in Fig. 3e). The former effect (d_{x^2−y^2}) indicates an increased probability of a Ni 1s to d_{x^2−y^2} transition, and therefore a decrease in the ground state occupancy of the d_{x^2−y^2} orbital.

Discussion

This work illustrates that the NNO MIT occurs without concurrent Ni charge ordering. Additionally, we observe a redistribution of charge from the Ni 3d to the Nd 5d states across the MIT. The redistribution of electronic density from the Ni d_{x^2−y^2} orbital occurs in films under tensile strain. In contrast, compressive strain shifts the d_{3z^2−r^2} energy lower, making it the preferentially occupied eg orbital. However, the d_{3z^2−r^2} orbital has less d-p\sigma overlap, and thus less oxygen hybridization. Consequently the compressive state is unlikely to present similar electron relocation. Because the MIT electron transfer mechanism is associated with films under tensile strain the occupation of the Ni d_{x^2−y^2} orbital and its’ greater hybridization with the O 2p orbitals may underlie the MIT mechanism.

This work reveals a process which may assist the insulating gap to open, as a result of Ni 3d localization. Two effects likely contribute to increased Ni 3d localization: the decrease in Ni electron occupation and the increase in Ni-O distance. The novel involvement of the A-site cation as an acceptor facilitates the charge transfer process resulting in Ni charge redistribution. Thus, the MIT is neither pure Mott-Hubbard, despite electron localization, nor simple charge-transfer. In addition, our results may aid in describing the proposed emergent mid gap state activity [12] through a partial transfer from Nd 5d states to the Ni-O hybridized conduction band in conjunction with the metallic phase onset.
Figure 4a) RIXS spectra from NNO/STO measured at a variety of incident energies. b) Incident RIXS energies. c) A sketch showing the compression induced splitting of the Ni e_g orbitals. One electron, partially donated by the O 2p, is shown in gray instead of black. d) RIXS spectra of NNO/STO and NNO/LAO measured at the Ni K pre-edge. The NNO/LAO spectra has degenerate e_g levels, and therefore one dd transition between t_2g and e_g levels. The NNO/STO e_g levels are split by tensile strain and therefore two dd transitions are observed. e) RIXS spectra of NNO/STO measured above and below the MIT. The low energy peak has higher intensity in the insulating phase as electron density from the d_{x^2-y^2} orbital shifts away from Ni to Nd.
