Introduction
Streptococcal toxic shock syndrome (STSS) is a condition that suddenly and rapidly progresses as a result of an infection with group A streptococcus (GAS; ie, *Streptococcus pyogenes*). This condition can lead to septic shock, acute respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), or multiple organ failure, which accounts for its high fatality rate. As reported, we encountered a case where GAS initially caused primary peritonitis and subsequently caused STSS. In the case in question, the patient’s life was likely saved by an emergency laparotomy followed by extensive peritoneal lavage and drainage.

Case Report
A 40-year-old woman was admitted to the Emergency Department of Aomori Prefectural Central Hospital for lower abdominal pain and numbness in the extremities that developed 14 hours prior. She was on day 6 of her menstrual cycle, had a temperature of 37.9 °C, a blood pressure of 92/46 mmHg, a heart rate of 97 beats/min, and an oxygen saturation of peripheral artery (SpO₂) of 96%. No abnormal skin findings were noted. The lower abdomen was tender, and peristalsis had diminished slightly. Blood test results were as follows: white blood cell (WBC) count of 8100/µL, hemoglobin (Hb) of 6.2 g/dL, platelet (PLT) count of 46.2 × 10⁹/µL, C-reactive protein (CRP) of 9.61 mg/dL, blood urea nitrogen (BUN) of 20.1 mg/dL, and creatinine of 1.52 mg/dL. Uterine fibroids, ascites, and thickening of the peritoneum were suggested, and intraabdominal hemorrhage was also a possibility, but computed tomography (CT) scan failed to reveal any obvious sources of bleeding. A pelvic infection was suspected, so the patient was admitted and azithromycin (AZM) 500 mg/d was started. However, 29 hours after initial presentation, abdominal pain intensified and the patient’s temperature increased to 38.4 °C. The patient continued to exhibit hypotension, breathing difficulties, and SpO₂ of 90% or lower. An intraabdominal hemorrhage or formation of a pelvic abscess was suspected after 32 hours of initial presentation, and the decision was made to perform an emergency laparotomy. Blood test results just prior to surgery were WBC count of 700/µL,
Hb of 7.8 g/dL, PLT count of 10.2 × 104/µL, CRP of 25.5 mg/dL, BUN of 35.2 mg/dL, and creatinine of 2.12 mg/dL. Systemic inflammatory response syndrome and renal dysfunction were manifested. A large volume of ascites that resembled pus and general peritonitis were manifested in the peritoneal cavity. Other than uterine fibroids, lesions were not evident in the uterus, ovaries, or fallopian tubes. The intestines were somewhat edematous, but no gastrointestinal problems, such as a gastrointestinal perforation and cholangitis, were noted. However, the greater omentum was very congested (Fig. 1). Peritoneal lavage and drainage was performed along with a partial omentectomy and an appendectomy. A peritoneal drain was placed and the abdomen was closed.

While she was managed on a ventilator, 1 g of meropenem three times a day (tid) was added to AZM. The total volume of transfusions from surgery until discharge from the intensive care unit was 24 units of packed red blood cells, 22 units of fresh frozen plasma, and 60 units of platelets, continuous hemodiafiltration was performed, direct hemoperfusion was performed with a polymyxin B-immobilized column, an immunoglobulin preparation was administered, and hemodynamics was managed with continuous intravenous infusion of noradrenaline. Blood test results about 10 hours after surgery revealed the following: WBC count of 21,000/µL, Hb of 10.1 g/dL, PLT count of 4.6 × 104/µL, CRP of 21.5 mg/dL, BUN of 36.4 mg/dL, creatinine of 2.15 mg/dL, total bilirubin of 1.83 mg/dL, aspartate aminotransferase of 699 IU/L, alanine aminotransferase of 226 IU/L, fibrin degradation product of 93.3 µg/mL, fibrinogen of 204 mg/dL, and prothrombin time of 24.6 seconds. Chest X-rays revealed infiltrated in the fields of both lungs, and ARDS, DIC, and soft tissue necrosis, and it can even lead to death. The virulence factors of GAS are far more varied than those of other bacteria, and the various exotoxins produced by GAS stimulate cytokine release and act as superantigens. A study of STSS isolates has suggested that specific genetic mutations allow GAS to evade elimination by the host’s neutrophils, causing a highly pathogenic disease characterized by fulminant infection.

According to a systematic review of 32 cases of primary peritonitis due to STSS, the median age for the development of STSS was 38 years (range: 23–87 years), female patients

**Figure 1.** Surgical findings. The greater omentum was very congested. Peritoneal lavage and drainage was performed along with a partial omentectomy and an appendectomy.

outnumber male patients at a ratio of 4:1, and 91% of patients were healthy with no underlying illness. According to the same systematic review, 16% of patients developed STSS from an ascending infection originating from vagina, 6% of patients developed it from pharyngitis, 9% of patients developed it from a droplet infection, and 69% of patients developed it via an unknown route.

In the current case, the patient was transported to the Emergency Department 14 hours after developing symptoms. When the patient was seen, she had a slight fever, and her vital signs stabilized, so STSS would have been an unlikely differential diagnosis. There is a room to discuss the appropriateness of performing an emergency laparotomy, while the patient had a WBC count as low as 700/µL. Nonetheless, purulent ascites were noted, and peritoneal lavage and drainage were performed. Peritoneal fluid was tested for bacteria about 70 hours after initial presentation, and the results revealed the presence of GAS. The patient was treated with antibiotics that GAS was susceptible to. This approach saved the patient’s life, so performing surgery was the correct choice in this case. However, necrosis in the distal extremities failed to improve. It may be a cause that Fasciitis due to gas gangrene irreversibly occurred.

Routes of infection have often cited an ascending infection originating from vagina. In the current case, infection occurred during menses, and a pedunculated tumor stained positive for Gram-positive bacteria, so the patient presumably had an ascending infection originating from vagina. If a patient complaining of lower abdominal pain has a fever or elevated inflammatory markers, further testing (which includes vaginal culture) must be performed prior to the administration of an antibiotic. This point was underscored by the current case. A recent report demonstrated a 6-year-old girl who initially presented with presumed viral gastrointestinal infection for a week and later developed catastrophic primary peritonitis and septic shock requiring resuscitation and emergency exploratory laparotomy due to group A streptococci. The incidence of STSS has increased over the past few years, so STSS must be kept in mind as potential diagnosis if a patient has abdominal symptoms that abruptly worsen.

**Author Contributions**

Wrote the first draft of the article: MYokoyama, YY. Contributed to the writing of the article: MYokoyama, AM, YY. Agreed the study results and conclusions: FO, AI, MYokota, DM, ST, TK, YN, TO. Jointly developed the structure and arguments for the article: MYokoyama, AM, YY. Made the critical revisions and approved the final version: FO, AI, MYokota, DM, ST, TK, YN, TO. All authors reviewed and approved the final article.
