2) the absence of any other pathogen; and 3) wound healing during appropriate, long-term antimicrobial drug treatment. However, the source of infection remained unknown. The patient had a tattoo on the skin flap used for the breast reconstruction, and ink has been shown to be a source for rapidly growing mycobacteria other than *M. conceptionense* (6). However, the tattoo was 5 years old and clinically safe.

Recent reports have identified 12 *M. conceptionense* isolates from water collected in a cooling tower (7) and 9 isolates from various freshwater fish species (8). The type strain of *M. conceptionense* had been isolated after prolonged exposure of the patient to fresh water (4). These observations suggest that water is a potential source for *M. conceptionense*. In this patient, use of contaminated aqueous solutions or inadequately rinsed surgical equipment (9) was unlikely the source of infection because further investigations indicated proper use of sterilized, non-reusable surgical equipment. At home, the patient used well water, but results of tests used to detect *M. conceptionense* by culture and the presence of the rpoB gene in well water remained negative.

Because *M. conceptionense* is an emerging pathogen with only 2 reported cases of infection (4,10), the optimal treatment is unknown (Table). Current recommendations for breast implant infection from *M. fortuitum* include 6 months of appropriate antimi-

This work was supported by Unité de Recherche sur les Maladies Infectieuses et Tropicales Emergentes UMR CNRS 6236 IRD 198.
December 28, 2009, we studied 20 patients with confirmed disease and 3 adult patients with suspected disease who met the US Centers for Disease Control and Prevention case definitions for pandemic (H1N1) 2009 (3). An RDT (QuickVue A+B; Quidel, San Diego, CA, USA) was performed by using nasopharyngeal swab specimens. Genetic material specific for pandemic (H1N1) 2009 viruses was detected in nasopharyngeal or throat swab specimens by real-time reverse transcription–PCR at the Centers for Disease Control and Prevention, Taiwan (4). Demographic and clinical characteristics of the 23 patients are shown in the Table.

Severity of illness was assessed within 24 hours of admission by determining the Acute Physiology and Chronic Health Evaluation II score (5). The highest Sequential Organ Failure Assessment score was calculated to predict outcome of critically ill patients during their stay in the intensive care unit (6). The Student t test was used to assess continuous variables, and χ² or Fisher exact tests were used to assess discrete variables. A p value <0.05 was considered significant. Statistical analyses were performed by using SAS software version 9.1 (SAS Institute, Cary, NC, USA).

There were no differences in age, sex, body mass index, underlying diseases, or occurrence of secondary bacterial infection between patients who received mechanical ventilation (n = 15) and those who did not (n = 8). There were no significant differences between the 2 groups in the median number of days from onset of illness to access to medical care. Patients receiving mechanical ventilation had higher severity-of-illness scores and longer times in the intensive care unit and the hospital. Sensitivity of the RDT was 100% for patients who did not receive mechanical ventilation and 26.7% for those who did (p<0.0001).

Median age of the 8 patients who received ECMO was 31 years. Only 3 patients had underlying diseases. RDT results were positive for only 1 of these patients. Five patients were tested by RDT more than one time before transfer or hospitalization. The interval from onset of illness to the first RDT was 1 d for 1 patient, 2 d for 4 patients, 3 d for 2 patients, and 6 d for 1 patient. Failure of the RDT to detect influenza was associated with a delay of ≥5 d in instituting antiviral therapy for 6 of 8 patients who received ECMO. However, ECMO was stopped for 7 patients who were discharged from hospital after a median duration of 23 d (interquartile range 11.5–54 d) of ECMO.

| Characteristic | No mechanical ventilation (n = 8) | Mechanical ventilation Non-ECMO (n = 7) | ECMO (n = 8) |

Human Brucella canis Infections Diagnosed by Blood Culture

To the Editor: Brucellosis is a worldwide zoonosis caused by Brucella spp. The 4 species known to infect humans are B. melitensis, B. suis, B. abortus, and B. canis (1). Since 1999, 11 cases in Japan have been reported. Although no bacteria were isolated, serum antibody detection indicated that 4 were caused by B. melitensis or B. abortus acquired abroad and the other 7 by B. canis (2). Of these 7 patients, 2 were presumed to have received their infection from dogs, and the sources of infection for the other 5 are unclear.

We report 2 cases of B. canis infection diagnosed by blood culture.

Patient 1 was a 71-year-old male pet shop manager with hypertension. He came to Chubu Rosai Hospital, Nagoya, Japan, on August 9, 2008, after having fever and fatigue for 3 weeks, which were nonresponsive to third-generation cephalosporins. At the time of admission, his temperature was 37.8°C, but physical examination findings were unremarkable. On day 2, gram-negative coccobacilli were detected in a culture of blood collected at the time of admission. Ceftriaxone (1 g 1×/d) was administered, but fever persisted. On day 5, coccobacilli were growing poorly on culture media. Because the patient's history indicated the possibility of a zoonotic disease, doxycycline (100 mg 2×/d) was administered. Thereafter, the patient's fever and generalized symptoms resolved. The blood specimen and isolated bacteria were sent to the National Institute of Infectious Disease, B. canis was identified by combinatorial PCR (3). Serum tube agglutination test indicated an antibody titer against B. canis of 1,280 (Table). On day 10, streptomycin (1 g 1×/d) was added to the treatment regimen. On day 33, the patient was discharged; his laboratory findings were unremarkable.

This report demonstrates an apparently paradoxical inverse relationship between a positive RDT result and severity of illness among patients with pandemic (H1N1) 2009. This observation cannot be explained by differences in the time to access to medical care, performance of RDT (7), or prior antiviral therapy. Variants of pandemic (H1N1) 2009 virus may preferentially infect the lower respiratory tract in certain hosts (8). Invasive properties of pandemic (H1N1) 2009 virus and severity of illness may be more closely related to heterogeneity in host immunity than to viral load (9). US Centers for Disease Control and Prevention guidance advises that “hospitalized patients with suspected influenza should receive immediate empiric antiviral treatment..., a negative RDT or DFA test result does not exclude influenza virus infection...” (10). Moreover, this guidance also recommends that collection of lower respiratory tract specimens may be useful for reverse transcription–PCR testing to improve diagnosis for patients suspected of having severe lower respiratory tract disease caused by pandemic (H1N1) 2009 virus. The current findings strongly support this recommendation, particularly for severely ill patients.
