Holocene variations in peatland methane cycling associated with the Asian summer monsoon system

Yanhong Zheng1,2, Joy S. Singarayer3, Peng Cheng4, Xuefeng Yu4, Zhao Liu4, Paul J. Valdes5 & Richard D. Pancost1

Atmospheric methane concentrations decreased during the early to middle Holocene; however, the governing mechanisms remain controversial. Although it has been suggested that the mid-Holocene minimum methane emissions are associated with hydrological change, direct evidence is lacking. Here we report a new independent approach, linking hydrological change in peat sediments from the Tibetan Plateau to changes in archaeal diether concentrations and diploptene δ13C values as tracers for methanogenesis and methanotrophy, respectively. A minimum in inferred methanogenesis occurred during the mid-Holocene, which, locally, corresponds with the driest conditions of the Holocene, reflecting a minimum in Asian monsoon precipitation. The close coupling between precipitation and methanogenesis is validated by climate simulations, which also suggest a regionally widespread impact. Importantly, the minimum in methanogenesis is associated with a maximum in methanotrophy. Therefore, methane emissions in the Tibetan Plateau region were apparently lower during the mid-Holocene and partially controlled by interactions of large-scale atmospheric circulation.
Atmospheric methane (CH$_4$) concentrations reached a maximum in the early Holocene (~10 ka BP) of ~700 p.p.b.v. and subsequently decreased to a minimum of ~550 p.p.b.v. during the mid-Holocene from 6 to 4 ka. However, the cause of the minimum remains controversial. Proposed mechanisms invoke the loss of the subtropical methane source, reduced emissions of low-latitude northern hemisphere monsoonal regions, drying of tropical wetlands and a decreased extent of both northern and tropical peatlands. These changes could be related to the behaviour of the intertropical convergence zone via its influence on monsoon systems (ITCZ). Insolation-driven summer monsoon variations have been invoked to explain glacial–interglacial variations in atmospheric CH$_4$ concentrations, and multiple lines of evidence also demonstrate a gradual decrease in Northern Hemisphere monsoon intensity over the Holocene. This appears to have caused drying of wetlands, and could have caused decreased methane emissions, through the Holocene; however, direct evidence is missing. To better understand CH$_4$ variations during the Holocene, and to understand how the Asian Monsoon (AM) could have influenced wetland methane dynamics, direct investigations of wetland deposits are required.

We have examined the impact of monsoon-driven hydrological change on methane cycling in Tibetan peats (Fig. 1c) using biomarker proxies for methanogen biomass and methanotrophy. Although wetland methane flux is governed by a range of factors such as water-table position, temperature, substrate quality and vegetation, the putative precipitation-based mechanisms described above bring about lower atmospheric CH$_4$ in the mid-Holocene via decreased methanogenesis. Consequently, records of methanogen biomass might serve as a direct test of these hypotheses. Methanogenesis, the biogenic production of CH$_4$ mediated by Archaea, is widespread in natural peatlands. Examination of microbially mediated CH$_4$ biogeochemical processes in ancient sediments is challenging; however, archaeal diether biomarkers have proved to be useful in studying methanogenic processes in peatlands. We compare archaeol and hydroxyarchaeol concentrations in a Tibetan Plateau peat to local evidence for bog wetness and regional records of precipitation to evaluate the linkages between the AM and methanogenesis and directly test proposed models for Holocene methane production. We complement our interpretation by evaluating changes in methanotrophy using bacterially derived hopanoid $\delta^{13}$C values. Our results indicate that variations in precipitation associated with the Asian summer monsoon (ASM) govern both methanogenesis and methanotrophy in Tibetan peats.

### Results

**Holocene variations of ASM precipitation.** The Hongyuan Peat was collected from the Northeastern Tibetan Plateau (32°46’N, 102°31’E; Fig. 1), and chronology was obtained by AMS $^{14}$C ages (See Methods). The Tibetan peatlands are the largest in China and the largest high-altitude marsh in the world, comprising 600,000 hectares, a small but significant component of the 530–570 mha of wetlands globally. They contribute between 0.56 and 1 Tg of methane emission per year, ~0.5–1% of the average annual global flux from wetlands (110 Tg). The Hongyuan peatlands are dominated by high-cold sedges, with Carex mulliensis and Kobresia humilis being the two major peat-forming species. C. mulliensis is one of the most abundant plant remains in Hongyuan peats. Other species include Polygonum viviparum and Chamaesiun paradoxum.

The Hongyuan peats contain a range of lipid biomarkers that are commonly observed in such settings, including bacterial and archaeal dialkyl glycerol diether (DAGE) lipids (such as archaeol and sn-2- and sn-3-hydroxyarchaeols, that are the focus of this investigation, as well as non-isoprenoidal DAGEs; Supplementary Fig. 1 and Supplementary Note 1) and glycerol dialkyl glycerol.

![Figure 1](image_url)
Previously obtained humification indices and $\delta^{13}$C values of *C. muliensis* cellulose from the same peat (but a different core, from within tens of metres) have been interpreted as proxies for peat wetness, and by extension the amount of precipitation—or more precisely the net precipitation—evaporation (P–E) balance—which is related to the ASM17,18 (Supplementary Note 2). In the Hongyuan Peat, both proxies record similar trends, indicating an interval of enhanced P–E from 11.5 to 6.4 ka BP, followed by a dramatic weakening from 6.4 to 4 ka BP, after which peat wetness increased again in the late Holocene but remained lower than that of the early Holocene (Fig. 2e,f).

This overall temporal pattern of decreasing precipitation during the Holocene resembles other Holocene precipitation records across the AM-influenced region, that is, Dongge Cave, southern China5 and Indian summer monsoon records19. Specifically, the Holocene optimum with maximum effective precipitation for the monsoon region occurs from 10.5 to 6.5 ka BP8. The long-term decrease in precipitation after 6 ka BP suggests that similar monsoon precipitation trends dominate over large areas. Indeed, modelled P–E for the region using the coupled ocean-atmosphere Hadley Centre climate model (HadCM3) also indicates a decreased effective precipitation through the Holocene (Fig. 3d).

However, the Hongyuan Peat $\delta^{13}$C values17 and humification records18 do not suggest only a monotonic decrease in Tibetan Plateau precipitation but instead document a long-term drying trend, coinciding with the low precipitation of the mid-Holocene from 6.4 to 4 ka BP.

**Figure 2 | Comparison of microbial lipid and Tibetan Plateau precipitation records.** (a) Archaeol records. (b) The ratio of archaeol to hopanol (Ar/Hopanol). (c,d) sn-2 hydroxyarchaeol (sn-2-OH-Ar) and sn-3 hydroxyarchaeol (sn-3-OH-Ar) concentrations. (e,f) Carex muliensis cellulose $\delta^{13}$C values17 as well as humification records18 from nearby cores in the same region. The yellow band represents lower concentrations of archaeol diether lipids coinciding with the low precipitation of the mid-Holocene from 6.4 to 4 ka BP.

Methanogenesis associated with ASM. In the Hongyuan Peat, archaeal concentrations vary between 1.5 and 35 μg g$^{-1}$ during the Holocene (Fig. 2a), being generally high during the early Holocene but low during the interval from ca. 6.4 to 4 ka BP. After 4 ka BP, they are variable but generally high, with peaks occurring at depths of 75–89 cm (1.5–1.8 ka BP) and 139–159 cm (2.8–3.3 ka BP). Although archaeol is relatively recalcitrant21,22, even being found in 50 million-year-old Eocene sediments23, it can be degraded in some settings24. If that was the case, we would expect concentrations to decrease downcore and that is not observed. Nonetheless, it is useful to constrain this by normalizing archaeol concentrations to a compound with a similar, that is hydroxylated, chemical functionality. The ratios of archaeol to hopanol (Ar/Hopanol) yield trends similar to those obtained solely from archaeol concentrations (Figs 2a,b and 4a). Hopanols in peat sequences have been argued to represent aerobic bacterial biomass, with lower concentrations being associated with higher water tables25. Therefore, the minimum in Ar/Hopanol ratios from ca. 6.4 to 4 ka is evidence for a minimum in the size of anaerobic, relative to aerobic, microbial populations, as well as evidence against downcore degradation of archaeol.

Hydroxyarchaeol also occurs in the Hongyuan peats as both the sn-2 and sn-3 isomers, but its concentration is much lower than that of archaeol. The presence of hydroxyarchaeol in these peats is consistent with microbiological characterizations of the nearby Zoige peat: both 16S rRNA and mcrA gene homology analyses show that *Methanosarcinales* and *Methanomicrobiales* constitute the majority of methanogens26, and hydroxyarchaeol is particularly abundant in species of the former27,28. The depth profiles of archaeal and hydroxyarchaeol concentrations are similar (Fig. 2a,c,d). However, a similarity of archaeol and hydroxyarchaeol depth profiles has not been observed in other settings and is unexpected. Archaeol is relatively recalcitrant and well preserved during diagenesis22, whereas hydroxyarchaeol appears to be poorly preserved2. Consequently, the former is typically interpreted as reflecting a mixture of living but mostly fossil biomass and the latter interpreted as predominantly deriving from living biomass.

This could indicate that both lipids reflect downcore changes in living methanogen biomass, which would be problematic for our interpretation of archaeol concentrations as indicative of past changes in methane cycling. We argue that this is unlikely because previous studies have consistently shown that the majority of methanogenesis occurs between 20 and 50 cm in peats29–31. This is related to the interaction of substrate quality...

Figure 3 | Methanogen biomass proxy and other records. (a) Archaeol and OH-Ar (hydroxyarchaeol) concentrations from the Tibetan peats. The decrease in methanogen biomass at ~6.4 ka likely reflects decreased CH₄ production and provides direct evidence for previous hypotheses that this caused lower CH₄ emissions. However, neither those models nor our archael ether lipid data account for possible changes in methanotrophy. To examine this, we have also determined the carbon isotopic composition of diploptene (Fig. 4b), a relatively taxonomically widespread bacterial hopanol that is produced by, but not exclusive to, methano- trophs10,38. The concentration of diploptene varies through the Hongyuan peat profile but does exhibit a maximum from 6.4 to

Figure 4 | Aerobic bacterial biomass proxy records. (a) The ratio of archaeal to hopanol (Ar/Hopanol). (b,c) Diploptene carbon isotopes and diploptene concentrations. The yellow band represents the mid-Holocene methanotrophy maximum.

The similarity in archaeal and hydroxyarchaeol profiles in the Hongyuan peat is because of remarkable preservation of the latter in this relatively cold setting.

Thus, features in the shallow Hongyuan peat, such as peaks in archaeal concentration in the upper 70 cm (latest Holocene), must be interpreted cautiously. Instead, we focus our interpretation on the pronounced minimum in archaeal diether concentrations (and Ar/hopanol ratios) that occurs between 6.4 and 4 ka. It is very difficult to envision a scenario in which this reflects the living methanogen population, and the broad similarity between archaeal diether lipid concentrations and climate proxies is remarkable. The minima in δ¹³C values of C. muliensis cellulose and humification records17,18 coinciding with minima in archaeal diether concentrations and Ar/hopanol ratios suggest a link between peat wetness and depth of the water-table level and methanogen biomass (Fig. 2). We argue that intervals with high concentrations of archaeal and hydroxyarchaeol are indicative of enhanced methanogen biomass, and by extension methanogenic activity, occurring under anaerobic, that is, relatively wetter climate conditions, and vice versa8 (Fig. 2). Markedly lower concentrations of archaeal diether lipids coincide with the low P–E of the mid-Holocene from 6.4 to 4 ka BP, recorded both elsewhere on the Tibetan Plateau and more widely in the AM region (Figs 1c and 3h–j). After 4 ka BP, the methanogen biomass increases again but varies markedly, possibly at millennial scales, although these shallow records could also reflect the influence of currently living organisms. This interval corresponds to a generally weak ASM but elevated Tibetan peatland wetness5,17,18 (Fig. 3g,h). Overall, a close linkage between precipitation and methanogenesis is consistent with investigations of the nearby Zoige wetland of the Tibetan Plateau, where archaeal community (methanogen) abundances are 10-times lower during drought years37.

Methanotrophy during the mid-Holocene. The decrease in methanogen biomass at ~6.4 ka likely reflects decreased CH₄ production and provides direct evidence for previous hypotheses that this caused lower CH₄ emissions. However, neither those models nor our archael ether lipid data account for possible changes in methanotrophy. To examine this, we have also determined the carbon isotopic composition of diploptene (Fig. 4b), a relatively taxonomically widespread bacterial hopanol that is produced by, but not exclusive to, methano- trophs10,38. The concentration of diploptene varies through the Hongyuan peat profile but does exhibit a maximum from 6.4 to
4 ka (Fig. 4c). This could be evidence for a larger aerobic bacterial population during a relatively dry climatic interval; however, given diptplemented's diverse sources, the increased concentration is not unambiguously indicative of a larger methanotroph population. Such insight can be provided by the carbon isotopic composition of diptplemented values, which effectively record the mass balance mixing of different (putatively heterotrophic and methanotrophic) sources. Diptplemented δ13C values vary dramatically, from −31.6‰ to −50.3‰ (Fig. 4b), with the lowest values (between −42.0‰ and −50.3‰) occurring from 6.4 to 4 ka (Fig. 4b). This depletion is striking and yet to be observed in modern peats, where carbon isotopic compositions range from −29‰ to −34‰ (refs 10,37,38). Previous workers have argued that diptplemented δ13C values as low as −34‰ could be evidence of a methanotroph contribution because the purely heterotrophic end member value appears to range from −20 to −30‰ (ref. 39). Therefore, the diptplemented δ13C values below −40‰ in the 6.4–4-ka interval indicate a relatively large methanotroph population.

Previous work suggests that lower diptplemented δ13C values, that is, elevated methanotrophy, are associated with greater methane fluxes. We observe the opposite here, with the mid-Holocene minimum in methanogen biomarker concentrations during a relatively dry interval corresponding to a maximum in the methanotrophic isotopic signature. Thus, we interpret the minimum in diptplemented δ13C values as a change in methane flux pathways at a time when overall methane production was lower. In many wetlands, CH4 is transported directly from deep soil (deeper than 20 cm) to the atmosphere by the passive CH4 flow induced by the aerenchyma of vascular plants. Indeed, the dominant sedge species of the Tibetan Plateau have been shown to mediate CH4 transport. Under such conditions, methanotrophy is limited and diptplemented δ13C values are expected to reflect a heterotrophic signature. Crucially, however, even in settings characterized by efficient CH4 oxidation, diptplemented δ13C values are rarely lower than −40‰ (ref. 10). Therefore, we suggest that the mid-Holocene methanotroph maximum in the Hongyuan peat reflects particularly efficient oxidation of methane.

The causes of increased methane oxidation are unclear but are likely related to concomitant changes in either water-table level and/or vegetation. As discussed above, the inferred decrease in P–E in the Hongyuan Peat was likely associated with a deeper watertable level. This would have been associated with deeper oxygen penetration and methane oxidation, possibly to depths below the rooted zone. If so, methane flux across the anoxic–oxic interface could have been predominantly diffusive, rather than advective through plant vascular systems, giving rise to a greater efficiency of methane oxidation. Alternatively or additionally, a plant community with a shallower root system could have the same impact. We have no direct evidence for a major change in peat type during the mid-Holocene; however, the percentage of wetland pollen is low during the period from 8 to 3 ka BP (ref. 45). Similarly, C29/C31 δ-alkane ratios and Pm ratios (Supplementary Note 3 and Supplementary Fig. 2) do vary in the peat profile, with a prolonged minimum in both occurring during the mid-Holocene. This is consistent with the expected shift towards peat vegetation assemblages typical of drier settings. However, it also suggests the development of longer and thicker sedge roots rather than the shallower roots associated with, for example, mosses, that would cause increased methane oxidation efficiency. It is possible that root-facilitated transport of O2 into the soil fostered increased CH4 oxidation in the rhizosphere. Therefore, we propose that the unexpectedly high methane oxidation efficiency arose from either a diffusive flux regime or rhizosphere oxidation associated with deeper roots, both of which are consistent with drier climatic conditions.

Discussion

Although peatland emissions are strongly modulated by a range of environmental and vegetation controls, the close correlation of methanogen biomass with bog wetness validates hypotheses that the mid-Holocene minimum in atmospheric methane was associated, at least in this region, with decreased peatland wetness and methanogenesis. Our methanotroph signatures further suggest that this lower methane production was associated with more efficient methane oxidation. Therefore, we conclude that there is a causal link between the ASI system and methane emissions from Asian wetlands through the Holocene. However, we note that the link is not simple: archaeol concentrations in the early and late Holocene are similar, whereas P–E is apparently higher in the early Holocene. Therefore, precipitation intensity is probably not the only control on methanogenesis.

To explore this further, we have compared our results to modelled Holocene temperature, precipitation and methane emissions from the Tibetan Plateau (Fig. 3d–f) and globally. In these simulations, emissions from low-latitude northern hemisphere monsoon regions increase in response to an orbitally induced decrease in summer insolation in the tropics (Fig. 3c), southwards migration of the ITCZ and an associated reduction in summer precipitation, in agreement with previous arguments. However, although the simulations indicate markedly lower methane emissions at 4 ka relative to 10 ka across SE Asia (Fig. 1b), they indicate only a modest decrease over the Tibetan Plateau (Figs 1a and 3). This could be indicative of a sensitive response at marginal AM settings that is recorded by sediments but not by our simulations.

These model results allow some extension of our findings to wider geographical regions. CH4 emissions in tropical soils, including but not limited to peat, are controlled by the water-table depth and this has been the basis for arguing that the atmospheric CH4 temporal trends should track that of monsoon precipitation. During the mid to late Holocene, the generally declining monsoon precipitation in China is consistent with that of orbital-scale CH4 variations, which are primarily controlled by the strength of tropical monsoons as well as with model predictions and our Tibetan wetland biomarker results. Thus, although wetlands in the Tibetan Plateau are not the largest sources of atmospheric CH4, the decreasing AM precipitation in China during the middle Holocene could be representative of the tropical Northern Hemisphere’s influence.

However, our modelled methane emissions for the Tibetan Plateau exhibit a decrease from 11 to 2 ka, which is largely driven by modelled cooling and decreased P–E (Fig. 3d–f); however, the humification indices and methanogen biomarker concentrations suggest that the minimum in P–E and methanogenesis occurred from 6.4 to 4 ka. It is possible that the methanogen biomarker record is biased in shallow peat by the presence of a surviving, modern methanogenic community, but that cannot fully explain the discrepancy because it is also apparent in the precipitation records (Fig. 3).

We suggest that orbitally forced climate simulations are capturing the widescale processes related to the AM that dictate precipitation and methanogenesis in soils across China (Fig. 1a,b), but that in the Tibetan Plateau secondary processes impose additional controls. In particular, the differences between the simulations and proxy records primarily arise from the 6- to 4-ka dry interval. This pronounced drying during the mid-Holocene is not restricted to Asia and has been inferred from lake and vegetation records in regions of Central America, Africa and North and South America. Thus, the more complex record in the Hongyuan Peat and elsewhere could indicate that areas at the margin of the monsoonal influence (that is, in the case of Hongyuan, being perched on the northern margin of the summer monsoon regime) are more vulnerable to ITCZ location.
The Nyryan Peat, therefore, appears to record a combination of local, regional and global forcings, and we have interrogated these by comparing modelling results with local proxy records. First, these suggest that the Tibetan Plateau became less methaneogenic during the mid-Holocene, presumably because of orbital forcing. This effect appears to have been even stronger elsewhere in East China (Fig. 1b). Second, this minimum in methane production was, at least in the Nyryan peat, associated with a non-intuitive increase in methanotrophy that we attribute to more efficient methane oxidation (under a diffusive rather than aerenchyma-facilitated advective transport regime). Third, a weakened ASM, especially in marginal regions and at the high elevation of the Tibetan Plateau, apparently brought about a mid-Holocene minimum in CH4 emission from about 6 to 4 ka.

Climate impacts on wetland extent and methanogenesis were likely not limited to the Tibetan Plateau, especially given the widespread, orbitally paced decrease in monsoon intensity through the Holocene44. Both northern and tropical peatland expansions slowed at ~5 ka and have been attributed to neoglacial cooling in high northern latitudes and weakening monsoons in low latitudes44. Crucially, evidence for a mid-Holocene dry interval is also widespread54–56. Therefore, the Tibetan peat data provide evidence of how monsoon-driven hydrological conditions could have more widely influenced CH4 emissions during the Holocene. We propose that CH4 emissions, at least in East Asia, were indeed controlled by interactions of large-scale atmospheric circulations, but modulated by regional factors, and that future work should explore the regional variation of these responses.

Methods

Site description. The Zoigè-Hongyuan Peat is located on the eastern edge of the Tibetan Plateau and is the largest peatland in China48. The average elevation of the peatland is 3,400 m a.s.l. and the Hongyuan Peat sampling site is 2 km southeast of Hongyuan County at 32°46’N, 102°31’E with an altitude of 3,507 m (Fig. 1c). The Hongyuan Peat covers an area of ~4,500 km2. The area is characterized by cold and wet climate and a long frost period. The annual mean temperature is ~1°C, the January mean temperature is approximately ~10°C and the July mean temperature is ~11°C. The annual mean precipitation is ~700 mm. The climate of this area is mainly controlled by the AM systems (Fig. 1c). The continuous Hongyuan Peat core was recovered using a Russian peat corer. The core is 75 cm long and consists of 584 cm of brown to dark-brown peat containing a large amount of undegraded plant residue, underlain by 6 cm of dark-brown mud and then 64 cm of dark-brown peat. Below 654 cm depth, the sediment is greyish-green to dark-brown mud, representing lacustrine depositional conditions. The core was subsampled in the laboratory at 1-cm intervals to conduct biomarker measurements.

Lipid biomarker analysis. Freeze-dried, homogenized samples were extracted by sonication with sequence of increasingly polar solvents: 3 × with dichloromethane (DCM), 3 × with DCM/methanol (1:1 v/v) and 2 × with methanol. The total lipid extracts were separated into neutral, free fatty acids and phospholipid fractions using an aminopropylsilyl bond eluate column (Biotage), cleaned before use with 18 ml.

AMS 14C dating and chronology. Sample pretreatment, AMS-target preparation and AMS measurement were all conducted at the State Key Laboratory of Loess and Quaternary Geology (SKLQQG). The pretreatment of samples for 14C dating was performed using the method of ref. 59: plant fragments with a size ranging between 90 and 300 µm were isolated from peat by wet sieving, and then subjected to an acid–alkali–acid (HCl–NaOH–HCl) treatment59. AMS targets were prepared from the pretreated samples, which were then placed with CuO powder into 9-mm quartz tubes, evacuated to <10−5 torr and then combusted. The CO2 was converted catalytically to graphite using Zn (Zn powder with added Fe powder as a catalyst)60. Dating was calibrated using the Calib61 programme61. The average value of the 2σ calibrated age range is quoted as the calibrated age. The calibrated ages provide a firm chronological framework for the past 13,000 years. The results of two separate parts of the studied section are least square-fitted to establish the chronological framework (Supplementary Fig. 3 and Supplementary Table 1).

Climate model. The Hadley Centre coupled ocean-atmosphere model, HadCM3, was used to perform equilibrium snapshot simulations for the Holocene. The simulations are equivalent to the ‘ALL’ experiment described in ref. 2, where each time-slice simulation has changed to boundary conditions ice-sheet volume, landsea mask, trace greenhouse gases and orbital configuration derived from palaeo data. Time slices were set up at 1-ka intervals for the Holocene and each was run for 500 years. The results of these simulations were used to produce counterclockwise-rotating biomarker experiments at the core.

Acknowledgements

We thank the OGU technical support (Alison Kuhl and James Williams), Dr. Edward Hornbrook and Gordon Inglis for suggestions on this manuscript, and Quyan Li and Zhangzhang Wang for field and laboratory assistance. R.D.P. acknowledges the Royal Society Wolfson Research Merit Award. We wish to thank NERC for partial funding of the mass spectrometry facilities at Bristol (contract no. R8/H10/63; www.ismfa.co.uk). This work was supported by a Marie Curie International Incoming Fellowship within the 7th European Community Framework Programme and the National Science Foundation Grant (4107204, 4137203).

Author contributions

The model work was carried out by J.S.S and P.J.V., and the AMS 14C age data were prepared by Small samples for 14C accelerator targets by catalytic reduction of CO2. Radiocarbon 29, 303–306 (1987).
