Lone-Pair-Induced Structural Ordering in the Mixed-Valent 0D Metal-Halides Rb$_{23}$Bi$_{3-x}$Sb$_{7-x}$Sb$_V^\text{V}$Cl$_{54}$ (0 ≤ x ≤ 7)

Bogdan M. Benin, Kyle M. McCall, Michael Wörle, Dominique Borgeaud, Thomas Vonderach, Kostiantyn Sakhatskyi, Sergii Yakunin, Detlef Günther, and Maksym V. Kovalenko

ABSTRACT: Mixed-valent metal-halides containing ns$^2$ lone pairs may exhibit intense visible absorption, while zero-dimensional (0D) ns$^2$-based metal-chlorides are generally colorless but have demonstrated promising optoelectronic properties suitable for thermometry and radiation detection. Here, we report solvothermally synthesized mixed-valent 0D metal-halides Rb$_{23}$Bi$_{3-x}$Sb$_{7-x}$Sb$_V^\text{V}$Cl$_{54}$ (0 ≤ x ≤ 7). Rb$_{23}$Sb$_{7-x}$Sb$_V^\text{V}$Cl$_{54}$ crystallizes in an orthorhombic space group (Cmcm) with a unique, layered 0D structure driven by the arrangement of the 5s$^2$ lone pairs of the Sb$_V^\text{V}$Cl$_{54}$ octahedra. This red material is likely the true structure of a previously reported monoclinic “Rb$_{23}$SbCl$_{54}$” phase, the structure of which was not determined. Partially or fully substituting Sb$_{7-x}$Sb$_V^\text{V}$Cl$_{54}$ with isoelectronic Bi$_{3-x}$ yields the series Rb$_{23}$Bi$_{3-x}$Sb$_{7-x}$Sb$_V^\text{V}$Cl$_{54}$ (0 < x ≤ 7), which exhibits a similar layered 0D structure but with additional disorder that yields a trigonal crystal system with an enantiomorphic space group (R32). Second harmonic generation of 532 nm light from a 1064 nm laser using Rb$_{23}$Bi$_{3-x}$Sb$_{7-x}$Sb$_V^\text{V}$Cl$_{54}$ powder confirms the noncentrosymmetry of this space group. As with the prototypical mixed-valent pnictogen halides, the visible absorption bands of the Rb$_{23}$Bi$_{3-x}$Sb$_{7-x}$Sb$_V^\text{V}$Cl$_{54}$ family are the result of intervalent Sb$_{7-x}$Sb$_V^\text{V}$ and mixed-valent Bi$_{3-x}$Sb$_V^\text{V}$ charge transfer bands (CTB), with a blueshift of the absorption edge as Bi$_{3-x}$ substitution increases. No PL is observed from this family of semiconductors, but a crystal of Rb$_{23}$Bi$_{3-x}$Sb$_{7-x}$Sb$_V^\text{V}$Cl$_{54}$ exhibits a high resistivity of 1.0 × 10$^{10}$ Ω·cm and X-ray photoconductivity with a promising $\mu$τ product of 8.0 × 10$^{-5}$ cm$^2$ s$^{-1}$ V$^{-1}$. The unique 0D layered structures of the Rb$_{23}$Bi$_{3-x}$Sb$_{7-x}$Sb$_V^\text{V}$Cl$_{54}$ family highlight the versatility of the ns$^2$ lone pair in semiconducting metal-halides, pointing the way toward new functional 0D metal-halide compounds.

INTRODUCTION

The vibrant colors of mixed-valent solid-state compounds have captivated chemists since the discovery of the famous Fe(II,III) pigment, Prussian blue, in the early 18th century. Subsequent studies have developed a rich chemistry of compounds with transition or post-transition metals in two distinct oxidation states, which exhibit unusual behavior including superconductivity, magnetic phase transitions, and an intervalence charge transfer band (CTB) in absorption.

While such mixed-valent materials come in a variety of structures and compositions, mixed-valent pnictogen halides exclusively exhibit cubic or tetragonal unit cells with the general formula, A$_2$M$^{III}$X$_{12}$ (A = K, Rb, Cs; M$^{III}$ = Sb, Bi, In, Tl; X = Cl, Br; Figure 1). These can be considered as transmutations of the vacancy-ordered double perovskites, A$_2$M$^{IV}$X$_6$ (e.g., M$^{IV}$ = Sn$^{9,10}$, Te$^{11}$, Pb$^{12}$) — a well-known 0D system in which M$^{IV}$X$_6$ octahedra are separated by regular vacancies and arranged with cations, such as Cs or Rb, into an antifluorite structure$^{13,14}$. In the mixed-valent pnictogen halides, the transmutation of the 4+ charge is achieved by doubling the cell and splitting half of the filled sites into a 3+ and the other half into a 5+, i.e., doubling the formula from...
Table 1. Summary of A$_4$M$_{III}$Sb$_V$X$_{12}$ Phases

| Composition          | Space group | a     | c     | Abs max (nm) | Ref.  |
|----------------------|-------------|-------|-------|--------------|-------|
| Cs$_4$Sb$_{II}$Sb$_{III}$Cl$_{12}$ | I4$_1$/amd  | 10.4650 (2) | 21.0095 (7) | 540.5 | 19,24,25 |
| Cs$_2$Bi$_{III}$Sb$_{III}$Cl$_{12}$ | I4$_1$/amd | 10.492 (2) | 21.1017 (6) | 417   | 24,25   |

A$_4$M$_{III}$X$_6$ to A$_4$M$_{III}$M$_{V}$X$_{12}$ (often written A$_4$M$_{III}$$_{0.5}$M$_{V}$$_{0.5}$X$_6$ to maintain the connection to the parent structure type). The first reported mixed-valent main group metal-halide of this type was the intensely indigo-colored Cs$_4$SbCl$_6$ first reported in 1882.15

The strong color of these compounds was unexpected because undoped, low-dimensional ternary chlorides containing either trivalent or pentavalent pnictogen metal-centers tend to be colorless both in solution and in the solid state.

The earliest reports on such phases mistakenly described the indigo-black Cs$_4$SbCl$_6$ and, later, the black Cs$_4$SbBr$_6$ as containing a tetravalent Sb cation;16,17 however, this oxidation state is unknown for Sb and the mixed-valent hypothesis began to gain traction. Magnetic measurements later demonstrated these materials to be diamagnetic, thereby confirming the mixed-valent composition Cs$_4$Sb$_{II}$Sb$_{V}$X$_{12}$,18 and the optical features of this mixed valency were first described in 1963 by Peter Day.7

These materials were then intensely investigated in the 20th century as a prototypical example of charge transfer (CT) in the solid state, due in part to the accessibility of their optical properties which lie in the visible spectrum.19,20 At this point, a growing library of A$_4$M$_{III}$M$_{V}$X$_{12}$ mixed-valent materials began to develop with various combinations of Sb$_V$ and M$_{III}$ (M$_{III}$ = Sb, Bi, In, Tl, Fe, and Rh) as well as bromides and chlorides,17,21 allowing for comparative studies of the optical and electrical properties as well as structures. On the basis of these observations and other works, Robin and Day published a seminal paper that put forth the Robin-Day classification of mixed-valence compounds, in which class I compounds have distinct sites with very stable, trapped lone pairs of electrons that lack mixed-valent transitions in the visible range, class II mixed-valent compounds offer distinguishable valences that possess sufficient orbital overlap to induce a visible mixed-valent absorption transition, and class III compounds have shared valencies on indistinguishable sites with minimal orbital delocalization.7

It was demonstrated that for the intensely colored Cs$_4$Sb$_{II}$Sb$_{V}$X$_{12}$ compositions containing Bi$_{III}$ and Sb$_{III}$, the CT occurs from the ns$^0$ orbital of the M$_{III}$ cation to the Sn$^0$ orbital of the Sb$^V$ cation, thereby explaining the shift in the CTB into the visible range.17,19 In contrast, In$_{III}$ and Tl$_{III}$ lack the lone pair and thus the ns$^0$ to ns$^0$ transition occurs at much higher energy, yielding a pale yellow color and a corresponding change from a Robin-Day class II mixed-valent system for A$_4$M$_{III}$X$_6$ compounds containing Sb$_{III}$ and Bi$_{III}$ to a class I system in those with In$_{III}$ and Tl$_{III}$17,19,21. The crucial nature of the lone pair was further demonstrated in a series of experiments in Cs$_4$Sb$_{II}$In$_{III}$,17,19 showing that the intensity of the CTB is proportional to the product of [Sb$_{III}$] and [M$_{V}$] concentrations, and hence was at its maximum intensity when the ratio [Sb$_{III}$]:[M$_{V}$] = 1 in both the solid state as well as in solution.7

The through-space or outer-sphere nature of the energy transfer was supported by both electrical conductivity and resistivity measurements as well as structural analysis. These materials form disconnected structures with nearly cubic symmetry, and the phases all tend to adopt either cubic structures, in which M$_{III}$ and Sb$_V$ sites are identical, or tetragonal structures with unique sites for M$_{III}$ and Sb$_V$ (Figure 1; Table 1).24 Importantly, there are no extended paths or chains through these 0D structures for CT; additionally, there are no aggregates such as dimers or trimers that could provide inner-sphere CT mechanism.1,28 This outer-sphere mechanism was further supported with the observation of high resistivities (10$^7$–10$^{15}$ Ω-cm) and negligible photoconductivity (Table S1 of the Supporting Information, SI).8,20,22 Electrical measurements within the series Cs$_4$Sb$_{III}$In$_{III}$Sb$_{V}$Cl$_{12}$, again showcased the importance of the ns$^0$ lone pair in this outer-sphere conduction pathway, as compositions with x > ~0.1 demonstrated electronic conductivity proportional to the product of [Sb$_{III}$] and [Sb$_V$] concentrations, while the pure In$_{III}$ composition, and those lacking sufficient Sb$_{III}$ to generate an outer-sphere charge pathway, exhibited high resistance and ionic conductivity.20

Although there is a large body of work related to the structures and properties of this family of materials, the structure and properties of the Rb–Sb$_{III}$–Bi$_{III}$–Sb$_V$–Cl phases remain unexplored. While the tetragonal Rb$_4$Sb$_{II}$Sb$_{V}$Br$_{12}$ is known (Table 1),22,23 the corresponding chloride has been reported to be either cubic,21 cubic yet slightly disordered,18 or to decompose into a reportedly monoclinic Rb$_2$SbCl$_6$ phase for which the structure is unknown.28,29 Furthermore, no reports exist on Rb$_4$Bi$_{III}$Sb$_V$Cl$_{12}$ or any related phase. In this work, we report the mixed-valent pnictogen halide series Rb$_2$Bi$_{III}$Sb$_{III}$–Sb$_V$–Cl$_{14}$ (0 ≤ x ≤ 7) and describe the structural and optoelectronic properties of these materials. The red Rb$_2$Sb$_{III}$–Sb$_V$–Cl$_{14}$ crystallizes in a unique, layered 0D structure driven by the arrangement of the Ss$^0$ lone pairs of Sb$_{III}$. Substitution with Bi$_{III}$ generates a solid solution of disordered variants of this structure, the Rb$_3$Bi$_{III}$–Sb$_{V}$–Cl$_{14}$ (0 < x ≤ 7) family, which exhibit large unit cells (V ≈ 16 000 Å$^3$) that are demonstrated to be noncentrosymmetric through second harmonic generation (SHG) measurements. The visible absorption of these materials is driven by CTBs of the M$_{III}$ ns$^0$ orbitals to Sb$_V$ Ss$^0$ orbitals although electrical measurements show Rb$_2$Bi$_{III}$Sb$_V$–Cl$_{14}$ to be a resistive semiconductor (1.0 × 10$^{10}$ Ω-cm) with a weak X-ray photoresponse ($\mu$C product of 8.0 × 10$^{-5}$ cm V$^{-1}$).
EXPERIMENTAL SECTION

Materials. Rubidium chloride (RbCl, 99+%) and hydrogen peroxide (H₂O₂, > 30%) were purchased from ACROS. Antimony (III) oxide (Sb₂O₃, 99%), bismuth(III) oxide (Bi₂O₃, 99.9%), and nitric acid (HNO₃, ≥ 65%) were purchased from Sigma-Aldrich. Hydrochloric acid (HCl, 37%) was purchased from VWR. All solids and acids were stored and handled under ambient conditions, while H₂O₂ was kept refrigerated. Inductively coupled plasma mass spectrometry (ICP-MS) reference standards of Rb, In, Sb, Ho, Ir, and Bi were purchased from Inorganic Ventures or Merck and were used to prepare tuning, calibration, and sample solutions. Concentrated nitric acid (>65 wt %; purified by double sub-boiling distillation), ultrapure Normatom hydrochloric acid (32–35 wt % purchased from VWR chemicals) and purified water (≥ 18.2 MΩ cm, Millipore, Billerica, U.S.A.) were used for the sample preparation. All chemicals were used as received without additional purification.

Stainless steel autoclaves from Parr instruments and Amat Equipment were utilized with PTFE containers for all solvothermal syntheses. Stainless steel autoclaves from Parr instruments and Amar Equipment purchased from VWR chemicals) and puri
cification flow of 1.06 L min⁻¹, a Plasma gas flow of 16 L min⁻¹, an auxiliary gas flow of 1 L min⁻¹, and a power of 1350 W.

The isotopes ⁸⁵Rb, ¹¹⁵In, ³¹⁰Sb, ¹⁶⁹Ho, and ⁲⁰⁰Bi were measured in the low resolution (m/Δm = 300) mode using the e-scan mode. Six runs and six passes were performed yielding a total measurement time of approximately 2 min per sample.

An external calibration was carried out. The limits of detection (LODs) for Rb, In, Sb, and Bi were determined to be 19.5 ng L⁻¹, 2.4 ng L⁻¹, 12.7 ng L⁻¹ and 0.7 ng L⁻¹, respectively. To validate the method and exclude any matrix effects, some samples were spiked with Rb, In, Sb, and Bi ICP reference standards. For additional details, see SI Note S1.

UV-visible Absorption Measurements. A Jasco V670 spectrophotometer equipped with an integrating sphere (ILN-725) was used to record diffuse reflectance spectra of microcrystalline powders. The absorption spectra were then calculated using a Kubelka–Munk (KM) transformation.

Second Harmonic Generation (SHG). Samples for SHG measurements were ground in a mortar and pestle and pressed between quartz slides, which were held together at the edges by a UV-curable resin. A Nd:YAG laser (Duetto from Time-bandwidth) with a wavelength of 1064 nm (10 ps pulses) was focused to a spot size of 50–100 μm on the sample. The focused laser was then moved along the powdered sample until a bright SHG active spot could be located. Second harmonic light was then detected with a fiber-coupled CCD spectrometer (CCS200 from Thorlabs).

X-ray Photoconductivity and I–V Measurements. A Keithley 236 source measurement unit was used to record I–V curves, crystals were contacted using Ag paint. For the characterization with X-rays, the Keithley 237 source measurement unit was used to apply a bias voltage while X-rays were generated using a Mini–X AmpTek X-ray tube with an accelerating voltage of 50 kV and an X-ray tube current of 50 μA.

RESULTS AND DISCUSSION

Red, hexagonal plates of Rb₂Sb₁₃SbVCl₅₄ were grown solvothermally from an HCl solution (Figure 2a). The crystals tend to grow together and stack, resulting in varying color intensities. Previously, two phases, the cubic Rb₅SbIII₂SbVCl₁₂ and the monoclinic Rb₂SbVI₄Cl₁₄ (equivalent to Rb₂Sb₃Cl₁₄ or Rb₂Sb₁₃SbVCl₅₄, not far off from the true stoichiometry), were reported to form in the Rb–SbIII/V–Cl compositional space. While the former was suggested to be cubic, it was also reported to decompose spontaneously at room-temperature to the monoclinic phase, which was observed to grow as hexagonal red platelets. At first glance, this agrees with the appearance of our crystals except that they do not exhibit geometrical effects. The fcc structure is utilized with PTFE containers for all solvothermal syntheses. This fcc structure is utilized to collect powder diffraction patterns. This fcc structure is utilized with a silicon strip MYTHEN 1K detector (Fa. DECTRIS), a curved Ge (111)-monochromator, and a Cu X-ray source (Cu Kα, λ = 1.5406 Å). For temperature-dependent PXRD measurements, a STADI P diffractometer (STOE & Cie GmbH, Darmstadt, Germany) in transmission mode (Debye–Scherrer geometry) was used to collect powder diffraction patterns. This fcc structure is utilized with a silicon strip MYTHEN 1K detector (Fa. DECTRIS), a curved Ge (111)-monochromator, and a Molybdenum X-ray source (λ = 0.70930 Å). The sample was sealed in a glass capillary, and diffraction patterns were measured at −173, −73, 25, and 200 °C.

Inductively Coupled Plasma Mass Spectrometry (ICPMS). The analysis was carried out using a sector-field inductively coupled plasma mass spectrometer (Element XR, ThermoFisher, Bremen, Germany). The solutions were introduced using a micro concentric nebulizer (200 μL min⁻¹, borosilicate glass, glass expansion) combined with a cyclonic spray chamber (borosilicate glass, glass expansion), quartz injector, torch with guard electrode, sampler, and skinner made of nickel. Further instrumental parameters were adjusted as follows: a nebulizer gas flow of 1.06 L min⁻¹, a Plasma gas flow of 16 L min⁻¹, an auxiliary gas flow of 1 L min⁻¹, and a power of 1350 W.

This temperature was held for 48 h before cooling back to RT at 2°C per hour. To ensure complete oxidation, the solution was heated to 70°C before cooling back to RT at 2°C per hour. To ensure complete oxidation, the solution was heated to 70°C before cooling back to RT at 2°C per hour. To ensure complete oxidation, the solution was heated to 70°C before cooling back to RT at 2°C per hour. To ensure complete oxidation, the solution was heated to 70°C before cooling back to RT at 2°C per hour.

Crystal X-ray Diffraction. Single-crystal X-ray diffraction (XRD) measurements were conducted at room temperature on a Bruker Smart, Bruker Smart Apex 2, and Oxford Xcalibur S. Each diffractometer is equipped with a molybdenum sealed-tube X-ray source (Mo Kα, λ = 0.7030 Å) and graphite monochromators. Multiscan CrysAlis PRO 1.171.39.31d (Rigaku Oxford Diffraction, 2017) was used for the absorption correction. Empirical absorption corrections were performed using spherical harmonics, implemented in SCALE3 ABSPACK scaling algorithm. Data was processed and integrated with CrysAlis PRO 1.171.39.31d (Rigaku OD, 2017), solved using SHELXT, refined using SHELXL through the Olex2 interface. Crystal structure images were generated using Vesta and Diamond software packages.

Powder X-ray Diffraction (PXRD) and Temperature-Dependent PXRD. A STADI P diffractometer (STOE & Cie GmbH, Darmstadt, Germany) in transmission mode (Debye–Scherrer geometry) was used to collect powder diffraction patterns. This fcc structure is utilized with a silicon strip MYTHEN 1K detector (Fa. DECTRIS), a curved Ge (111)-monochromator, and a Cu X-ray source (Cu Kα, λ = 1.5406 Å). For temperature-dependent PXRD measurements, a STADI P diffractometer (STOE & Cie GmbH, Darmstadt, Germany) in transmission mode (Debye–Scherrer geometry) was used to collect powder diffraction patterns. This fcc structure is utilized with a silicon strip MYTHEN 1K detector (Fa. DECTRIS), a curved Ge (111)-monochromator, and a Molybdenum X-ray source (λ = 0.70930 Å). The sample was sealed in a glass capillary, and diffraction patterns were measured at −173, −73, 25, and 200 °C.
birefringence, which would suggest either the presence of twins or a higher symmetry axis such as that found in a nearly cubic system.

Surprisingly, single crystal XRD at room temperature reveals that Rb\textsubscript{23}Sb\textsuperscript{III}\textsubscript{7}Sb\textsuperscript{V}\textsubscript{2}Cl\textsubscript{54} adopts an orthorhombic structure with the \textit{Cmcm} space group (\(a = 22.3435\) Å, \(b = 12.9057\) Å, \(c = 37.0625\) Å; Figure 2; Tables S2–S5). This structure, while also consisting of zero-dimensional MX\textsubscript{6} octahedra separated by Rb\textsuperscript{+}, significantly deviates from those observed for other M\textsuperscript{III}-Sb\textsuperscript{V} systems, in which the structures adopt a cubic or tetragonal unit cell with all octahedra effectively aligned along one of the unit cell axes (Figure 1). In contrast, the octahedra in Rb\textsubscript{23}Sb\textsuperscript{III}\textsubscript{7}Sb\textsuperscript{V}\textsubscript{2}Cl\textsubscript{54} arrange into layers with distinct orientations: these layers stack along \(c\) in a repeating ABC-C'\textsuperscript{'}B\textsuperscript{'}A\textsuperscript{'} sequence, where C'B'A' are related to ABC by a glide plane (Figure 2b). This stacking, the Sb\textsuperscript{III}Cl\textsubscript{6} and Sb\textsuperscript{V}Cl\textsubscript{6} octahedra in slab I and slab III are aligned with their faces along the \(a-b\) plane while the octahedra in slab II (comprised entirely of Sb\textsuperscript{V}Cl\textsubscript{6}) are rotated so that they lie on their edges, and slabs III', II', and I' are related by symmetry to slabs I, II, III (best viewed along the (210) plane, Figure 2b). Slabs I and III are also differentiated from slab II by their contents: each contains one Sb\textsuperscript{V}Cl\textsubscript{6} octahedra for every three Sb\textsuperscript{III}Cl\textsubscript{6} octahedra (aligned along the \(b\)-axis) while slab I has none, yielding the composition Rb\textsubscript{23}Sb\textsuperscript{III}\textsubscript{7}Sb\textsuperscript{V}\textsubscript{2}Cl\textsubscript{54} (Figure 2c). This composition was further supported by ICPMS measurements (Table S6).

There are four antimony sites in this structure with three distinct geometries and sizes: sites Sb1 and Sb2 comprise slab II and exhibit similar disphenoidal distortions due to the stereoactive 5s\textsuperscript{2} lone pair of Sb\textsuperscript{III}, while Sb3 and Sb4 make up slabs I and III. Sb3 exhibits a trigonal lone pair distortion and Sb4 (the Sb\textsuperscript{V} site) possesses a nearly perfect octahedron (Figure 2d). The average Sb–Cl bond lengths of Sb1 (2.660 Å), Sb2 (2.644 Å), and Sb3 (2.647 Å) are consistent with those of other Sb\textsuperscript{III}Cl\textsubscript{6} octahedra in the literature (e.g., 2.637 Å...
in Rb$_{23}$Bi$_{7}$Sb$_{3}$Cl$_{16}$, while that of Sb$_4$ is significantly smaller at 2.345 Å, supporting the assignment of SbV on this site (Table S7). Within slabs I and III the [SbVCl$_6$]$^-$ octahedra of Sb$_4$ are surrounded by six [SbCl$_6$]$^{3-}$ octahedra, with an average Sb···Sb distance of 7.50 Å and no Rb cations directly between them (Figure S1). The SbIII octahedra in Rb$_{23}$Bi$_{7}$Sb$_{3}$Cl$_{16}$ are slightly more distorted than those in Rb$_{7}$Sb$_3$Cl$_{16}$, suggesting greater lone-pair stereoactivity.

The origin of the layered Rb$_{23}$Bi$_{7}$Sb$_{3}$Cl$_{16}$ structure is the confluence of the lone-pair repulsion between the Sb$_{7}$ ions and the templating effect of the smaller Rb$^+$ cation. The Sb$_{7}$ sites exhibit longer bonds in the direction of Bi$(7s^2)$ lone-pair expression, shown in purple to highlight the direction of the lone-pair expression, and the repulsion of these lone-pairs leads to the arrangement shown in Figure 2e. The lone-pair expression of the Sb$_{7}$ octahedra in slabs I and III are aligned against each other pointing toward slab 2, pushing the Sb$_{3}$ octahedra slightly in the other direction.

This two-layer ordering precludes the addition of a third layer with trigonal Sb$_{7}$ slabs, as the resulting distortion would express lone pairs toward one or the other layers and cause repulsion. Thus, slab II consists of disphenoidally distorted Sb$_{7}$ octahedra (an unusual coordination for Sb$_{7}$, usually only observed as part of an edge-shared Sb$_{7}$X$_{10}$ dimer, e.g., Rb$_{7}$Sb$_{7}$X$_{16}$) with octahedra oriented differently than the other two slabs, these effects express the lone pairs in-plane so as to avoid repulsion with those of the other two slabs, thus driving the overall 3-fold ordering of this complex structure.

To further understand the origin of this new structure type, which deviates significantly from those of the A$_4$M$_{II}$M$_{V}$X$_{12}$ phases, we examined the coordination environments of Rb in this structure, as the A-site cations are considered the structure-directing atoms in related systems. By assigning each unique Rb-site a different color according to its coordination number (Figure S2), the structure-directing effect of the Rb polyhedra becomes evident (Figure S3a). Given the much stronger bonding between Sb–
Cl as compared to Rb–Cl, some Rb atoms are forced to sacrifice their coordination number to satisfy the overall stoichiometry, resulting in coordination numbers ranging from 6 to 12 (Table S8). The 6-fold coordinated Rb are squeezed into a trigonal prism around which the surrounding layer is ordered (Figure S3b,c). Although Rb is known to adopt 6-fold octahedral coordination in simple Rb-halide binary compounds, 6-fold coordination is not commonly observed in ternary metal halides. Furthermore, trigonal prismatic 6-fold coordination is even rarer. One such example is Rb$_6$CdBr$_6$ (ICSD 39621), which exhibits pseudotrigonal prismatic 6-fold coordination as a result of a $5^\circ$ twist. We consider this unusual Rb-halide geometry to most likely occur in Rb$_3$Sb$^{III}$-Sb$^V$Cl$_4$, as a result of lone-pair expression in Sb$^{III}$ octahedra. Note that the lone pairs of the three neighboring Sb$^{III}$Cl$_6$ octahedra all point toward this special site (Figure S3b,c), while the bond valence sums of these disphenoidal Sb sites are less than 3 (Table S7). This indicates that the excess charge of the expressed lone pair is partially shared by this seemingly underoxidant was substituted for H$_2$O$_2$, which could be more readily oxidant was substituted for H$_2$O$_2$, which could be more readily

While the Sb$^{III}$ valence sums of these disphenoidal Sb sites are less than 3 (Table S7), their lattice contraction and expansion without any evidence for a change in unit cell size, octahedral separation, and electronic configuration. Our initial attempts were centered on obtaining the reported phase-pure product. Nitric acid, for example, is known to be a strong oxidizing agent that can oxidize Sb$^{III}$ to Sb$^{V}$. While the Sb$^{III}$ to Sb$^{V}$ distance can be as low as 7.085(3) Å ($D$ to yield the tripled unit cell, where $O$ denotes an ordered 3-slab unit (Figure 3b). These slabs alternate in the mixed such that the location of the Sb$^5+$ octahedra in these slabs cannot be identified except by the significantly shorter average bond of the site (Figure 3c, Table S5). The smallest of the octahedra in the ordered layers are again those containing only Sb$^{V}$, which have a average bond length of 2.322 Å, and the remaining two sites exhibit trigonal and disphenoidal distortions due to the Sb$^{V}$ lone pair (Figure 3c, Table S20).

Given that the previously mentioned and published mixed-valent structures all exhibited either cubic or tetragonal unit cells at room temperature, we created a structure field diagram to observe how these new structures could be related to the other known compositions. This was prepared by comparing the A/X and B/X size ratios for different symmetries and compositions (Figure 3d). On the basis of this diagram it is clear that the nonexistent “Rb$_2$Sb$^{III}$Sb$^{V}$Cl$_{14}$ and the newly found Rb$_2$Bi$_{III}$Sb$^{III}$-Sb$^V$Cl$_4$ series occupy an otherwise empty region distinct from the other cubic and tetragonal phases. Furthermore, these crystals, like the red Rb$_{25}$Sb$_4$Cl$_{44}$, examination, it became evident that in these cases two phases were present and that colorless Rb$_{25}$Bi$_{13}$Sb$_3$Cl$_{16}$ crystals had nucleated and served as a substrate for the intergrowth of smaller, red crystals (Figure 3a). The structure of this red material was determined by single crystal X-ray diffraction on a crystal similar to that shown in Figure 3a. This material was found to crystallize in a trigonal crystal system with the R32 space group with a unit cell that is unexpectedly large for a fully inorganic material ($a = b = 12.95670(10)$ Å, $c = 111.7130(14)$ Å, $V = 16241.4(3)$ Å$^3$, Tables S13–S15). We note that an inversion twin law was used to solve this enantiomorphous structure, as this compound crystallizes in a racemic mixture. Refining mixed occupancies on each M$^{III}$ site in the structure (Table S16), we determined the composition of this red phase to be Rb$_x$Bi$_{13}$Sb$_3$Cl$_{16}$ with the Bi:Sb ratio corroborated by ICPMS analysis (Table S6).

Further adjusting the Sb$^{III}$ and Bi$^{III}$ precursor ratios, we were able to synthesize a solid solution that exists among all the M$^{III}$ octahedra of this structure to obtain the series Rb$_x$Bi$_{y}$Sb$_z$-Sb$^V$Cl$_4$ ($0 < x < 7$), which were all found to crystallize in the same trigonal space group as the mixed-metal samples. More specifically, the fully Bi$^{III}$ substituted endmember, Rb$_x$Bi$_{13}$Sb$^V$Cl$_4$, crystallizes into pale orange hexagonal plates with the R32 space group with $a = b = 12.9752(6)$ Å, $c = 112.438(8)$ Å, $V = 16393.5(18)$ Å$^3$ (Figure 3a,b; Figure S7; Tables S17–S20). As before, an inversion twin law was used to refine this structure as a racemic mixture of two enantiomers. Note that while the single crystal refinement yields a stoichiometry of Rb$_2$Bi$_{19}$Sb$_{25}$Cl$_{36}$, the ICPMS results (Table S6) yield a Bi:Sb ratio of 3.5(1), corresponding to the Bi-saturated composition Rb$_2$Bi$_{13}$-Sb$^V$Cl$_4$.

This 0D structure contains metal-halide octahedra and adopts layers that stack in 3-slab units akin to those of Rb$_2$Sb$^{III}$Sb$^{V}$Cl$_{16}$ but this structure exhibits disorder in every other 3-slab unit (Figure 3b). These slabs alternate in the rhombohedral symmetry in the sequence O–D–O’–D’–O–D to yield the tripled unit cell, where O denotes an ordered 3-slab layer and D denotes a disordered layer. This disorder is characterized by a 3-fold rotationally disordered site with 1/3 occupancy of the Cl atoms in three disphenoidally distorted Bi$^{III}$ octahedra (Bi6), with the neighboring site (Bi4/Sb4) mixed such that the location of the Sb$^{V}$ octahedra in these slabs cannot be identified except by the significantly shorter average bonds of the site (Figure 3c, Table S5). The smallest of the octahedra in the ordered layers are again those containing only Sb$^{V}$, which have an average bond length of 2.322 Å, and the remaining two sites exhibit trigonal and disphenoidal distortions due to the Sb$^{V}$ lone pair (Figure 3c, Table S20).

Given that the previously mentioned and published mixed-valent structures all exhibited either cubic or tetragonal unit cells at room temperature, we created a structure field diagram to observe how these new structures could be related to the other known compositions. This was prepared by comparing the A/X and B/X size ratios for different symmetries and compositions (Figure 3d). On the basis of this diagram it is clear that the nonexistent “Rb$_2$Sb$^{III}$Sb$^{V}$Cl$_{14}$ and the newly found Rb$_2$Bi$_{III}$Sb$^{III}$-Sb$^V$Cl$_4$ series occupy an otherwise empty region distinct from the other cubic and tetragonal phases. Furthermore, these crystals, like the red Rb$_{25}$Sb$_4$Cl$_{44}$...
Figure 4. Structural relationship between orthorhombic Rb$_{23}$Sb$_9$Cl$_{54}$ and trigonal Rb$_{23}$Bi$_7$Sb$_2$Cl$_{54}$. (a) Layer-by-layer breakdown showing one-to-one mapping of MCl$_6$ octahedra in each layer, with Mattfeld notation denoting the occupancy of AMX composition in each octahedral environment. (b) Unit cell of each structure viewed along the b-axis with Rb atoms removed for clarity, highlighting the offset stacking of Sb$^V$ octahedra in Rb$_{23}$Bi$_7$Sb$_2$Cl$_{54}$ that yields a tripped lattice constant c for the rhombohedral structure relative to orthorhombic Rb$_{23}$Sb$_9$Cl$_{54}$. (c) Unit cells of each structure’s disphenoidal layer (II) viewed along the c-axis, showing the mapping of the a and b axes of both unit cells.

The relationship between “O” slabs in Rb$_{23}$Bi$^{III}$Sb$^V$_2Cl$_{54}$ and the Rb$_{23}$Sb$^V$Cl$_{54}$ structure are clear as these slabs are identical to one another. By describing the compositions of the constituent planes in the “D” slabs with the same Mattfeld notation, it also becomes apparent that the subunits of each slab are equivalent (Figure 4a). Slabs IV and VI of the D-trilayer reduce to the same 103 and 010 compositions as I’ and III’ in Rb$_{23}$Sb$_7$Cl$_{54}$; furthermore, slab V has a composition of 506 and 136 (when considering occupancy), which reduces to the same 502 and 112 atoms as slab II’ in Rb$_{23}$Sb$_7$Cl$_{54}$ (Figure 4a). The relations between each crystallographic site in these two structures is described in the SI Note S2, Tables S7, S16, and S20.

The tripling of the c-axis of the R32 structure relative to that of Rb$_{23}$Sb$_9$Cl$_{54}$ is a result of the different stacking of the Sb$^V$ and Sb$^{III}$ octahedra along the a-axis, with the orthorhombic structure deriving from aligned Sb$^V$ octahedra while those of Rb$_{23}$Bi$_7$Sb$_2$Cl$_{54}$ shift by one octahedral unit (1/3 of the structure), such that it takes three repetitions to achieve an equivalent layer (Figure 4b). Finally, the relations of the a and b axes can be observed by examining the mapping of the ordered slab II with each unit cell (Figure 4c). Clearly, the disorder present within the structure forces the selection of an alternate unit cell and changes the symmetry, but it does not affect the underlying structural building blocks or the overall composition. This may be because both Bi$^{III}$ and Sb$^{III}$ possess ns$^5$ lone pairs, thus substitution alters the size of individual M$^{III}$Cl$_{6}$ octahedra while the ordering of the M$^{III}$Cl$_{6}$ and Sb$^{V}$Cl$_{6}$ octahedra is maintained.

Given the unusually large unit cells of the structures in the Rb$_{23}$Bi$_{7-x}$Sb$_2$Cl$_{54}$ series and the enantiomorphic nature of this space group, we measured SHG to check whether we had correctly ascribed the R32 space group to Rb$_{23}$Bi$_7$Sb$_2$Cl$_{54}$. Briefly, R32 is one of the space groups that allows for the occurrence of piezoelectricity. Effects such as piezoelectricity and SHG are related to the symmetry of the structure rather than the chemical composition, and hence serve as a good
evidence for noncentrosymmetry in a structure. To examine this property, we exposed a polycrystalline powder of Rb$_{23}$Bi$_{7}$Sb$_{2}$Cl$_{54}$ to a pulsed 1064 nm laser (10 ps pulse duration).

A powder is well suited as it contains all possible crystal orientations thus there will be some grains where crystal axes orient toward the incident beam according to a phase-matched condition, required for the SHG process. While scanning the focused laser beam (50−100 μm spot size) across the sample, some areas would produce visible green spots. Spectrally, this SHG emission occurs as a sharp line located exactly at 532 nm (Figure 5a). Furthermore, the intensity of this peak is expected to have a quadratic power dependence. When log(intensity) was plotted against power, a line with a slope of 2 was found, further confirming the lack of centrosymmetry in Rb$_{23}$Bi$_{2}$Sb$_{2}$Cl$_{54}$ and supporting the assignment of the R32 space group (Figure 5b).43,44

Structurally, very little changes between the Bi$^{3+}$ only, Bi$^{3+}$ rich, and Bi$^{3+}$ poor samples, as observed by the similarities of the crystallographic sites in each structure (Tables S7, S16, and S20). The Sb$^{5+}$ octahedra remain in the same position and the overall superstructure corrugation is still observable. This solid solution that exists within Rb$_{23}$Bi$_{7-x}$Sb$_{2}$Cl$_{54}$ is demonstrated by the linear dependence of the c-lattice parameter on the ratio of Bi$^{3+}$/Sb$^{3+}$ (Figure 6a). While the changes to composition within the Rb$_{23}$Bi$_{7-x}$Sb$_{2}$Cl$_{54}$ series do not strongly affect the structure, they do affect the energy of the CTB that gives these phases their intense colors (Figure 6b). For example, Rb$_{23}$Bi$_{6}$Sb$_{3}$Cl$_{54}$ is a light-yellow crystal (inset image in Figure 6a); this can also be observed from the KM spectra measured for a series of compositions in the Rb$_{23}$Bi$_{x}$Sb$_{7-x}$Sb$_{2}$Cl$_{54}$ series (Figure 6b). From these, it can be concluded that Bi$^{3+}$−Sb$^{5+}$ and Sb$^{3+}$−Sb$^{5+}$ CT interactions occur at visibly different energies, with the Sb$^{3+}$−Sb$^{5+}$ interaction at lower energy. However, they appear to be too close in energy and too broad to deconvolute the spectra and meaningfully describe the contributions of each transition to the overall spectral shape.

Having confirmed the structures of these materials and having observed CTB tunability, we turned our attention toward potential applications for these materials. Considering the existence of the visible CTB, we further examined if any of these materials exhibited photoluminescence (PL). While no reports have indicated that M$^{3+}$/Sb$^{5+}$ mixed-valent materials exhibit any PL, previous studies on Wolfram’s red salt (WRS;
[Pt(C2H5NH3)4][Pt(C2H5NH3)4Cl4·H2O], and N,N-di-methylaminobenzylidine-1,3-indandione (DMABI) have found evidence of emission from localized self-trapped CT excitons (STCCTEs). In the case of DMABI, this was observed around 2.5 eV at RT; whereas, WRS exhibited an emission peak around 1.15 eV at 4.2 K.\(^{35,46}\) In both cases, the emission was reported to be very weak (<0.1% quantum yield for DMABI).\(^{37}\) Furthermore, recent reports of efficient luminescence from S\(^{2-}\) lone pairs\(^{37}\) encouraged the investigation of potential emission in the Rb\(_2\)Bi\(_{7-2x}\)Sb\(_x\)Cl\(_{14}\) family, Rb\(_2\)Bi\(_{7-2x}\)Sb\(_x\)Cl\(_{14}\) samples with various compositions were cooled to 12 K and excited in the UV as well as in the CTB region to search for visible PL. (450–850 nm). No PL was observed in this range, regardless of excitation (ranging from 250 to 600 nm), at any temperature down to 12 K. Therefore, we also examined the possibility of IR emission at 77 K. Samples were cooled in a cryostat and illuminated at specific wavelengths from 250 to 600 nm with a Xe lamp equipped with a monochromator. An IR detector (In\(_1\)Ga\(_3\)) was utilized with several long pass filters to exclude scattered light from the lamp. No emission was observed from any Rb\(_2\)Bi\(_{7-2x}\)Sb\(_x\)Cl\(_{14}\) samples. Given the lack of visible emission in these systems, we also investigated the dilution of Sb\(_{IV}\) centers with both In\(_{III}\) and Bi\(_{III}\) by targeting the Rb\(_2\)Bi\(_{7-2x}\)In\(_{2x}\)Sb\(_x\)Cl\(_{14}\) system. One reaction incidentally yielded a new oxychloride phase, Rb\(_2\)Bi\(_{7-2x}\)Cl\(_{14}\) (Figure S9; Tables S22–S25). Aside from this, pure phases seldom formed, and no PL was observed down to 77 K in all cases.

We then investigated the electrical properties of these mixed-valent semiconductors. Previously, Day et al. had characterized the electrical properties of several A\(_{x}\)M\(_{VII}\)M\(_{V}\)X\(_{12}\) phases and investigated photoconductivity.\(^{20}\) They found that all investigated phases were highly resistive with conductivity that increased with temperature, identifying these materials as wide-gap semiconductors (Table S1). The character of the conductivity shifts from electronic in the A\(_{x}\)Sb\(_{VII}\)Sb\(_{IV}\)Cl\(_{12}\) compounds, where it is driven by an outer-space charge transfer process from Sb\(_{IV}\)Cl\(_4\) to Sb\(_{IV}\)Cl\(_4\) followed by Sb\(_{IV}\)Cl\(_4\) excited state migration among Sb\(_{VII}\)Cl\(_4\) octahedra, to ionic in the case of Cs\(_2\)In\(_{VII}\)Sb\(_{IV}\)Cl\(_{12}\), which lacks the active lone pair and thus has significantly higher resistivity.\(^{20}\) Also, no significant photoconductivity or changes to conductivity were observed under O\(_2\) or H\(_2\).

I–V curves were only measured for Rb\(_2\)Bi\(_{7-2x}\)Sb\(_x\)Cl\(_{14}\) as single crystals of suitable size could not be grown for other compositions. This material has a resistivity of 1.0 × 10\(^{10}\) Ω cm, 1–4 orders of magnitude lower than the A\(_{x}\)M\(_{VII}\)M\(_{V}\)X\(_{12}\) compounds (Table S1), indicating that the greater percentage of ns\(^{-}\)containing M\(_{VII}\) in the Rb\(_2\)Bi\(_{7-2x}\)Sb\(_x\)Cl\(_{14}\) structure promotes the formation and migration of charge-transfer electronic bands (Figure S10a). Instead, the resistivity of Rb\(_2\)Bi\(_{7-2x}\)Sb\(_x\)Cl\(_{14}\) is on par with values measured for other low-dimensional ns\(^{-}\)-based pnictogen-halides such as Rb-Sb-Cl\(_{16}\) or the A\(_{x}\)M\(_{VII}\)X\(_{2}\) series.\(^{34,48,49}\) Following these measurements, visible light photoconductivity was also examined but, similarly to previously reported mixed-valent compounds, no significant response could be detected.

We additionally considered the utility of these phases in X-ray detection. In several recent reports, highly resistive metal-halides such as the 0D Cs\(_2\)Bi\(_{7}\)I\(_8\) or the 2D (NH\(_2\))\(_2\)Bi\(_{7}\)I\(_8\) have been presented as possible alpha-particle and X-ray detector materials (ρ = 2.79 × 10\(^{10}\) Ω cm for Cs\(_2\)Bi\(_{7}\)I\(_8\)).\(^{50–52}\) The benefit of using low- and zero-dimensional materials of this type is that they will have very low noise under bias due to the intrinsically high resistivity.\(^{14,44}\) Exposing the Bi-rich single crystal Rb\(_2\)Bi\(_{7}\)Sb\(_x\)Cl\(_{14}\) (with a thickness of 0.36 mm) to X-rays from a Ag X-ray source operating at 50 kV resulted in a measurable photoreponse that could be fit with the single-carrier Hecht model (Figure S10b). Doing so yields a mobility-lifetime (μτ) product of 8.0 × 10\(^{-5}\) cm\(^2\)V\(^{-1}\). The quality of the fit to the single-carrier Hecht model indicates that one carrier type is dominant in this material, similar to the case of the leading semiconductor γ radiation detector Cd\(_{1−x}\)Zn\(_x\)Te (CZT), which exhibits a significant difference in the charge transport of electrons and holes.\(^{53}\) Note that we cannot distinguish whether our μτ value corresponds to the charge transport properties of holes or electrons on the basis of this measurement alone due to the high penetration of X-rays that generate electron–hole pairs throughout the detector thickness. Surprisingly, while this unoptimized μτ product does not match that of CZT at 4 × 10\(^{-3}\) cm\(^2\)V\(^{-1}\),\(^{53}\) it is quite competitive with other candidate radiation detector materials such as Pbl\(_2\),\(^{54}\) Hg\(_2\)Se\(_2\),\(^{55}\) and Bi\(_2\),\(^{53}\) which have each demonstrated spectroscopic gamma-ray response despite low μτ products on the order of 10\(^{-3}\) cm\(^2\)V\(^{-1}\). Compared with leading 0D materials, the μτ product of Rb\(_2\)Bi\(_{7}\)Sb\(_x\)Cl\(_{14}\) is only one order lower than the best value reported for Cs\(_2\)Bi\(_{7}\)I\(_8\) (7.97 × 10\(^{-4}\) cm\(^2\)V\(^{-1}\)).\(^{51}\) The sensitivity and detection limit for Rb\(_2\)Bi\(_{7}\)Sb\(_x\)Cl\(_{14}\) at 1.1 V μm\(^{-1}\) were determined to be 32.2 μC Gy\(_{air}\) \(^{-1}\) cm\(^{-2}\) and 25.3 μGy\(_{air}\) s\(^{-1}\), respectively. For comparison, a-Se, which is utilized commercially for X-ray detection, has a sensitivity and detection limit of 20 μC Gy\(_{air}\) \(^{-1}\) cm\(^{-2}\) and 5.5 μGy\(_{air}\) s\(^{-1}\), respectively at 10 V μm\(^{-1}\); CZT exhibits a sensitivity and detection limit of 318 μC Gy\(_{air}\) \(^{-1}\) cm\(^{-2}\) and 50 μGy\(_{air}\) s\(^{-1}\), respectively, at 0.1–1 V μm\(^{-1}\).\(^{56}\) Although this performance is not state-of-the-art, it is the first-of-its-kind for mixed-valent semiconductors and may offer a new route toward discovering X-ray semiconductor detector materials. Further performance improvements are expected from optimization of the size and quality of Rb\(_2\)Bi\(_{7}\)Sb\(_x\)Cl\(_{14}\) single crystals, as well as from improvements to device architecture, and future work toward this end is underway.

### CONCLUSIONS

After over a century of research on the A\(_{x}\)M\(_{VII}\)M\(_{V}\)X\(_{12}\) family of mixed-valent alkali pnictogen halides, new phases can still be discovered within this compositional space. We demonstrated that the combination of Rb, Sb\(_{VII}\), Sb\(_{IV}\), and Cl results in the orthorhombic Rb\(_{2}\)Sb\(_{VII}\)Sb\(_{IV}\)Cl\(_{14}\), a 0D mixed-valent compound with a unique layered structure type with octahedral ordering defined by the orientation of the stereoeactive S\(^{2-}\) lone pairs. Substitution of Sb\(_{VII}\) by Bi\(_{III}\) generates a family of Rb\(_{2}\)Bi\(_{VII}\)Sb\(_{IV}\)Cl\(_{14}\) (0 ≤ x ≤ 7) materials that crystallize in the noncentrosymmetric R32 space group. This noncentro-symmetry was confirmed by the observation of SHG with a 1064 nm laser. Furthermore, the charge-transfer absorption band in the visible range was tunable from dark red to pale yellow through M(III) substitution. Finally, Rb\(_{2}\)Bi\(_{VII}\)Sb\(_{IV}\)Cl\(_{14}\) single crystals were demonstrated to be high resistivity semiconductors that unexpectedly exhibited X-ray photo-response with a μτ product of 8.0 × 10\(^{-5}\) cm\(^2\)V\(^{-1}\) despite no efforts to optimize the crystal quality or device structure. These compounds present a wholly new structure type with prominent lone-pair expression coexisting with mixed-valency, highlighting the importance of the sizes of Rb\(^{+}\) and ns\(^{-}\)-based
MCl₆ octahedra that together induces the formation of this structure over the high-symmetry octahedral environments of the mixed-valent pnictogen halides, A₄M₄M'X₁₂. The novel composition and ordering in the Rb₂₃Bi₄Sb₇−₁ₓSbCl₁₄ₓ family leads to different orbital overlap relative to their high-symmetry contemporaries, as evidenced by the disparate colors of red Rb₂₃Sb₇−₁ₓSbCl₁₄ₓ and indigo Cs₆Sb₇−₁ₓSbCl₁₂, indicating nontrivial differences in the outer-sphere charge transfer processes of these new compounds. The X-ray detection exhibited by unoptimized Rb₂₃Bi₄Sb₇−₁ₓSbCl₁₄ₓ also indicates that mixed-valent materials may have potential in high-energy radiation detection applications. Beyond simply adding a new entry to the growing library of 0D metal halides, the complexity of this structure offers ripe opportunities for tuning and improving these materials; namely, the ability to tune both lone-pair expression as well as the charge transfer absorption band characteristic of mixed-valent materials within the same structure.
