ABSTRACT

It has been recently proposed that the observed grouping of either the perihelia and the orbital planes of some observed distant Kuiper Belt Objects (KBOs) can be explained by the shepherding influence of a remote (150 au $\lesssim q_X \lesssim$ 350 au), still unseen massive object PX having planetary size ($5 \, m_\oplus \lesssim m_X \lesssim 20 \, m_\oplus$) and moving along an ecliptically inclined (22 deg $\lesssim I_X \lesssim$ 40 deg), eccentric (380 au $\lesssim a_X \lesssim$ 980 au) Heliocentric bound orbit located in space at 80 deg $\lesssim \Omega_X \lesssim$ 120 deg and which is anti-aligned (120 deg $\lesssim \omega_X \lesssim$ 160 deg) with those of the considered KBOs. The trajectory of Saturn is nowadays known at essentially the same accuracy level of the inner planets due to the telemetry of the Cassini spacecraft. Thus, the expected perturbations $\dot{\sigma}$, $\dot{\Omega}$ due to PX on the Kronian apsidal and draconitic orbital motions are theoretically investigated to tentatively constrain the configuration space of PX itself. To this aim, we compare our predictions $\dot{\sigma}_{\text{theo}}$, $\dot{\Omega}_{\text{theo}}$ to the currently available experimental intervals of values $\Delta \dot{\sigma}_{\text{obs}}$, $\Delta \dot{\Omega}_{\text{obs}}$ determined by astronomers in the recent past without explicitly modeling and solving for PX itself. As such, our results, despite being plausible and in agreement to a large extent with other constraints released in the literature, should be regarded as proof-of-principle investigations aimed to encourage more accurate analyses in future. It turns out that the admissible region in its configuration space is moderately narrow as far as its position along its orbit, reckoned by the true anomaly $f_X$, is concerned, being concentrated around approximately 130 deg $\lesssim f_X \lesssim$ 240 deg. PX is certainly far from its perihelion ($f_X = 0$ deg), in agreement with other recent studies. The future analysis of the data from the ongoing New Horizons mission might be helpful in further constraining the scenario considered here for PX. Its impact on the spacecraft’s range over a multi-year span is investigated with a preliminary sensitivity analysis.

keywords Oort Cloud–Kuiper belt: general–celestial mechanics–ephemerides–gravitation

1. Introduction

Recently, indirect evidence for a distant body, dubbed\(^1\) PX or X in the following for simplicity, having planetary size and lurking in the outskirts of the Solar System has been claimed once more (Batygin & Brown 2016a). This time, its putative existence has been inferred from its possible shepherding gravitational action on some of the observed distant Kuiper Belt Objects (KBOs) which turned out to exhibit a peculiar grouping pattern either in the values of their arguments of perihelia $\omega$ (Trujillo & Sheppard 2014) and in the physical

\(^1\)Here and in the following, “X” is used with the meaning of “unknown”, not as the Roman numeral for ten.
space itself (Batygin & Brown 2016a). Its physical and orbital features originally put forth by Batygin & Brown (2016a) are resumed in Table 1. Later, Brown & Batygin (2016) explored the parameter space of the hypothesized planet in more depth by allowing for a certain range of variability in its possible physical and orbital features as a result of several numerical simulations of the dynamical evolution of different populations of KBOs. Examples of such an enlarged parameter space are displayed from Table 2 to 3. Furthermore, Bailey, Batygin & Brown (2016) suggested that a distant pointlike perturber with the characteristics envisaged in Brown & Batygin (2016) may explain the observed obliquity of the Sun’s equator as well as the specific pole position of the Solar spin axis from a nearly aligned initial state.

The publication of the seminal paper by Batygin & Brown (2016a) gave vent to a lingering flood of works dealing with several different aspects concerning such a revamped version of the time-honoured hypothesis that the Sun has more planet(s) than those currently known; see, e.g., Cowan, Holder & Kaib (2016); Fortney et al. (2016); Kenyon & Bromley (2016); Bromley & Kenyon (2016); Bailey, Batygin & Brown (2016); Mustill, Raymond & Davies (2016); Saillenfest et al. (2016); Philippov & Chobanu (2016); Dark Energy Survey Collaboration et al. (2016); Petit et al. (2016); Nesvorný, Vokrouhlický & Roig (2016); Chen et al. (2016); Lee & Chiang (2016); Wervx et al. (2016); Kaib & Sheppard (2016); Sheppard, Trujillo & Tholen (2016); Linder & Mordasini (2016); Fienga et al. (2016a); Paučo & Klačka (2016); Ginzburg, Sari & Loeb (2016); Raymond et al. (2016); Malhotra, Volk & Wang (2016); Lai (2016); Gomes, Deienno & Morbidelli (2016); Sivaram, Kenath & Kiren (2016); Beust (2016); Lawler et al. (2016); Li & Adams (2016); Gaiazzo et al. (2016); Holman & Payne (2016a,b); Veras (2016); de la Fuente Marcos & de la Fuente Marcos (2016a,b,c); de la Fuente Marcos, de la Fuente Marcos & Aarseth (2016); Martínez-Barbosa et al. (2017); Michalęy & Loeb (2016); Sheppard & Trujillo (2016); Toth (2016); Shankman et al. (2016); Batygin & Brown (2016b); Gratia & Fabrycky (2017), and counting.

In this work, we propose to independently put to the test such an intriguing scenario by looking at the perturbing effects that such a hypothesized distant planet would induce on the orbital motion of Saturn. Indeed, the ringed gaseous giant is the farthest known major body of the Solar System for which extended data records, whose level of accuracy is nowadays comparable with that of the inner planets thanks to the multi-year precise radiotracking to the Cassini spacecraft, are available.

In particular, we will attempt to preliminary narrow the configuration space of the putative remote planet of the Solar System by looking at the secular precessions of the Kronian longitudes of the perihelion $\sigma$ and of the node $\Omega$ induced by a distant pointlike perturber and at the most recent observational determinations of the rates of such orbital elements of Saturn. Such an approach is novel, being complementary to that recently followed by Fienga et al. (2016a), who suitably re-processed the radiotracking ranging data to the Cassini spacecraft collected over the the decade 2004-2104 by explicitly modeling the gravitational pull exerted by the putative new planet, and produced new residuals of the Earth-Saturn range. Also Holman & Payne (2016b) looked at the Cassini range measurements by simulating them under the action of the hypothesized distant
perturber. Then, they contrasted their fictitious ranges with those of the INPOP ephemerides used in [Fienga et al. (2016a)] in a least-square fashion by producing a set of simulated post-fit range residuals.

As far as the denomination of such a still undiscovered major body of the our planetary system, several names have become more or less popular over the years in either the specialized literature and in popular accounts. The late entrant in the literature is Planet Nine, so that the subscript “9” is often appended to the symbols denoting its physical and orbital parameters; it would have been likely Planet Ten if Pluto had not been demoted from planet status in 2006. Given the remarkable distance envisaged by [Batygin & Brown (2016a); Brown & Batygin (2016)] for it, we propose the name Telisto\(^2\) which, among other things, circumvents any possible future classification issues and addresses specifically a distinctive feature of the hypothetical body under consideration.

The paper is organized as follows. In Section 2 we introduce the corrections to the standard nodal and apsidal precessions of Saturn determined from observations with some of the most recent planetary ephemerides by independent teams of astronomers. Our analytical model for the long-term rates of change of the node and the pericenter induced by a distant, pointlike perturber is elucidated in Section 3. Our preliminary constraints from the Kronian perihelion and node on the perturber’s position along its orbit are inferred in Section 4. Section 5 contains a discussion of the method adopted in Section 4 by comparing it to other approaches followed in the literature. Constraints on the mass of PX are posed in Section 6 from the Kronian orbital precessions, independently of the KBOs-based assumptions by [Batygin & Brown (2016a); Brown & Batygin (2016)]. The possibility of using the ongoing telemetry of New Horizons, a further complementary feature of this work with respect to [Fienga et al. (2016a); Holman & Payne (2016b)], is discussed in Section 7. Section 8 summarizes our findings.

Finally, as a general consideration on the method adopted, we remark that, since, as discussed in more detail in Section 5 the orbital precessions of Saturn which we use in the present study were determined without explicitly modeling the dynamical action of PX, the results of the current analysis should be considered as proof-of-principle investigations aimed to encourage more accurate future studies. On the other hand, despite their necessarily preliminary character, it turns out that the bounds obtained by us are plausible and compatible to a non-negligible extent with those inferred in existing studies in which genuine solve-for data reductions were performed.

\(^2\)From τηλιστος: farthest, most remote. It should not be confused with Τελεστό, Telesto, a minor deity of the Greek mythology, whose name was given in 1983 to one of the irregular small satellites of Saturn (http://www.cbat.eps.harvard.edu/iauc/03800/03872.html). Ours is just a suggestion which we unpretentiously offer to the astronomical community. See Gingerich (1958) for an interesting historical account on how Uranus and Neptune finally took their current names after their discoveries. For Pluto, see Rincon (2006). It can be seen that not always the names originally proposed by their discoverers actually became of common usage.
2. The supplementary perihelion and node precessions

Table 4 lists the most recent determinations of the admissible intervals of values $\Delta \dot{\varpi}_{\text{obs}}, \Delta \dot{\Omega}_{\text{obs}}$ for potential anomalous perihelion and node precessions $\Delta \dot{\varpi}, \Delta \dot{\Omega}$ of Saturn obtained by two independent teams of astronomers (Pitjeva & Pitjev 2013; Fienga et al. 2011, 2016b) by processing long observational records collected during the last century without modeling the gravitational pull of any additional major body with respect to the known ones. Such observations-based ranges for the Kronian supplementary apsidal and nodal precessions $\Delta \dot{\varpi}, \Delta \dot{\Omega}$ with respect to the standard ones due to known dynamical effects of either Newtonian and relativistic nature are statistically compatible with zero. Thus, they can be used to put tentative bounds on the planetary orbital perturbations exerted by a still unmodelled pointlike object by comparing them to the corresponding theoretical predictions $\dot{\varpi}_{\text{theo}}, \dot{\Omega}_{\text{theo}}$ for the precessions caused by such a kind of perturber on a particle at heliocentric distance $r$. Equation (9) and Equation (13) in Iorio (2012), derived from a perturbing potential (Hogg, Quinlan & Tremaine 1991) accurate to order $O\left(\frac{r^2}{r_X^2}\right)$, are just what we need since they yield analytical expressions for the long-term precessions due to a distant pointlike perturber $X$ whose orbital period is assumed to be much longer than that of the perturbed planet. Such formulas are functions of either the orbital elements of the perturbed test particle and of the position unit vector $\hat{r}^X$ of $PX$, and they have a general validity since they hold for arbitrary orbital geometries of both the perturbed and the perturbing bodies.

3. The analytical model for the perihelion and node precessions due to a distant, pointlike perturber

Here, we offer an outline of the procedure followed to obtain Equation (9) and Equation (13) in Iorio (2012).

The perturbing potential by Hogg, Quinlan & Tremaine (1991) is

$$U_X = \frac{G m_X}{2r_X^3} \left[ r^2 - 3 \left( \hat{r} \cdot \hat{r}^X \right)^2 \right].$$

In order to analytically work out the long-term orbital perturbations induced by Equation (1), it has, first, to be evaluated onto the Keplerian trajectory of the disturbed test particle, characterized by

$$r = a(1 - e \cos E),$$

$$x = r (\cos \Omega \cos u - \cos I \sin \Omega \sin u),$$

$$y = r (\sin \Omega \cos u + \cos I \cos \Omega \sin u),$$
\[ z = r \sin I \sin u, \] (5)

where \( E, \ a, \ e, \ I, \ \Omega, \ u \) are the eccentric anomaly, the semimajor axis, the eccentricity, the inclination to the reference \( \{x, y\} \) plane, the longitude of the ascending node, the argument of latitude of the test particle, respectively. The latter one is defined as \( u = \omega + f \), in which \( \omega \) is the argument of pericenter, and \( f \) is the true anomaly connected with \( E \) through

\[ \cos f = \frac{\cos E - e}{1 - e \cos E}, \] (6)

\[ \sin f = \frac{\sqrt{1 - e^2} \sin E}{1 - e \cos E}. \] (7)

Then, the average over an orbital period \( P_b = \frac{2\pi}{n_b} \) of the test particle has to be calculated by means of

\[ \frac{dt}{dE} = \frac{1 - e \cos E}{n_b}; \] (8)

the orbital elements of PX entering \( r_X, \ \hat{l} \) have to be kept constant, as it is justified by the assumed much larger distance \( r_X \) with respect to \( r \) (see the discussion at the end of the present Section).

Finally, one obtains

\[ \langle U_X \rangle \doteq \left( \frac{n_b}{2\pi} \right) \int_0^{P_b} U_X \, dt = \frac{Gm_Xa^2}{r_X^3} \mathcal{U} \left( I, \ \Omega, \ \omega; \hat{l}^X \right), \] (9)

with

\[ \mathcal{U} \doteq -(2 + 3e^2) \left( -8 + 9\hat{l}_x^2 + 9\hat{l}_y^2 + 6\hat{l}_z^2 \right) - 120e^2 \sin 2\omega \left( \hat{l}_x \cos \Omega + \hat{l}_y \sin \Omega \right) \left[ \hat{l}_z \sin I + \right. \]

\[ \left. + \cos I \left( \hat{l}_x \cos \Omega - \hat{l}_x \sin \Omega \right) \right] - 15e^2 \cos 2\omega \left( 3 \left( \hat{l}_x^2 - \hat{l}_y^2 \right) \cos 2\Omega + 2 \left( \hat{l}_x^2 + \hat{l}_y^2 - 2\hat{l}_z^2 \right) \sin^2 I - \right. \]

\[ \left. - 4\hat{l}_x \sin 2I \left( \hat{l}_x \cos \Omega - \hat{l}_x \sin \Omega \right) + 6\hat{l}_x \hat{l}_y \sin 2\Omega \right] - 6 \left( 2 + 3e^2 \right) \left( \hat{l}_x^2 - \hat{l}_y^2 \right) \cos 2\Omega \sin^2 I + \]

\[ + 2\hat{l}_x \sin 2I \left( \hat{l}_x \cos \Omega - \hat{l}_x \sin \Omega \right) + 2\hat{l}_x \hat{l}_y \sin^2 I \sin 2\Omega \right] - 3 \cos 2I \left( 2 + 3e^2 \right) \left( \hat{l}_x^2 + \hat{l}_y^2 - 2\hat{l}_z^2 \right) + \]

\[ + 5e^2 \cos 2\omega \left[ (\hat{l}_x^2 - \hat{l}_y^2) \cos 2\Omega + 2\hat{l}_x \hat{l}_y \sin 2\Omega \right]. \] (10)

In Equation (10), \( \hat{l}_x, \ \hat{l}_y, \ \hat{l}_z \) are to be intended as the components of \( \hat{l} \).

As far as the longitude of the ascending node \( \Omega \) is concerned, the Lagrange planetary equation for its long-term variation (Bertotti, Farinella & Vokrouhlicky 2003)

\[ \left\langle \frac{d\Omega}{dt} \right\rangle = - \frac{1}{n_ba^2 \sqrt{1 - e^2} \sin I} \frac{\partial \langle U_{\text{pert}} \rangle}{\partial I}, \] (11)
computed by means of Equations (9) to (10), allows to obtain Equation (9) of Iorio (2012) for the long-term precession of the node due to a distant, pointlike perturber as

\[ \dot{\Omega}_{\text{theo}} = -\frac{G m_X}{4 a_X^3 n_b \sqrt{1 - e^2}} N(I, \Omega, \omega; \mathbf{l}), \]

(12)

with

\[ N = 3 \csc I \left[ \hat{I}_c \cos I + \sin I (-\hat{I}_y \cos \Omega + \hat{I}_x \sin \Omega) \right] \left\{ -2 \hat{I}_z \sin I + \cos I \left[ -2 + e^2 (-3 + 5 \cos 2 \omega) \right] (\hat{I}_y \cos \Omega - \hat{I}_x \sin \Omega) + e^2 \left[ \hat{I}_c (-3 + 5 \cos 2 \omega) \sin I - 5 \sin 2 \omega (\hat{I}_x \cos \Omega + \hat{I}_y \sin \Omega) \right] \}. \]

(13)

The Lagrange planetary equation for the long-term rate of change of the longitude of the pericenter \( \varpi \approx \Omega + \omega \) (Bertotti, Farinella & Vokrouhlický 2003)

\[ \left\langle \frac{d \varpi}{d t} \right\rangle = -\frac{1}{n_b a^2} \left\{ \left( \sqrt{1 - e^2} \right) \frac{\partial(U_{\text{pert}})}{\partial e} + \frac{\tan (I/2)}{\sqrt{1 - e^2}} \frac{\partial(U_{\text{pert}})}{\partial I} \right\} \]

(14)

can be used to derive our \( \varpi_{\text{theo}} \) by replacing \( U_{\text{pert}} \) with Equations (9) to (10). Thus, we finally get Equation (13) of Iorio (2012) for the long-term apsidal precession induced by a distant pointlike disturbing body, which is

\[ \varpi_{\text{theo}} = \frac{G m_X}{128 a_X^3 n_b \sqrt{1 - e^2}} \left[ \mathcal{G}(I, \Omega, \omega; \mathbf{l}) + \mathcal{H}(I, \Omega, \omega; \mathbf{l}) \right], \]

(15)

where

\[ -\frac{\mathcal{G}}{24(1-e^2)} = 8 - 9 \hat{I}_x^2 - 9 \hat{I}_y^2 - 6 \hat{I}_z^2 - 10 \left( \hat{I}_x^2 + \hat{I}_y^2 - 2 \hat{I}_z^2 \right) \cos 2 \omega \sin^2 I + 8 \hat{I}_c \cos \Omega \sin I \left[ \hat{I}_y \cos I (-3 + 5 \cos 2 \omega) - 5 \hat{I}_x \sin 2 \omega \right] + \cos 2 \Omega \left[ -3 \left( \hat{I}_x^2 - \hat{I}_y^2 \right) \left( 5 \cos 2 \omega + 2 \sin^2 I \right) - 40 \hat{I}_x \hat{I}_y \cos I \sin 2 \omega \right] - 8 \hat{I}_z \sin I \left[ \hat{I}_x \cos I (-3 + 5 \cos 2 \omega) + 5 \hat{I}_y \sin 2 \omega \right] \sin \Omega + 2 \left[ -3 \hat{I}_x \hat{I}_y \left( 5 \cos 2 \omega + 2 \sin^2 I \right) + 10 \left( \hat{I}_x^2 - \hat{I}_y^2 \right) \cos I \sin 2 \omega \right] \sin 2 \Omega - \cos 2 I \left[ 3 \left( \hat{I}_x^2 + \hat{I}_y^2 - 2 \hat{I}_z^2 \right) + 5 \cos 2 \omega \left[ \left( \hat{I}_x^2 - \hat{I}_y^2 \right) \cos 2 \Omega + 2 \hat{I}_x \hat{I}_y \sin 2 \Omega \right] \right], \]

(16)
and

\[ \mathcal{H} = -96 \left[ \hat{l}_z \cos I + \sin I \left( -\hat{l}_y \cos \Omega + \hat{l}_x \sin \Omega \right) \right] \left(-2\hat{l}_z \sin I + \cos I \left[ -2 + e^2 \left(-3 + 5 \cos 2\omega \right) \right] \left(\hat{l}_y \cos \Omega - \hat{l}_x \sin \Omega \right) + e^2 \left[ \hat{l}_z \left(-3 + 5 \cos 2\omega \right) \sin I - 5 \sin 2\omega \left(\hat{l}_x \cos \Omega + \hat{l}_y \sin \Omega \right) \right] \right] \tan \left( I/2 \right). \] (17)

As far as the validity of the assumptions on which Equation (9) is based, the standard relation between \(t\) and \(f\)

\[ n_b (t - t_p) = 2 \arctan \left( \sqrt{\frac{1 - e}{1 + e}} \tan \frac{f}{2} - \frac{e \sqrt{1 - e^2} \sin f}{1 + e \cos f} \right), \] (18)

allows to infer that, for the orbital configuration of Table 1, the true anomaly \(f_X\) changes of about \(\Delta f_X \approx 10\) deg over \(\Delta t = 100\) yr, which is just the length of the data records processed to obtain the supplementary orbital precessions of Table 4; even smaller angular ranges \(\Delta f_X\) for \(f_X\) can be obtained for either smaller values of \(e_X\) or larger values of \(a_X\). Since the lingering uncertainty in \(f_X\) is much larger than \(\Delta f_X\), according to both the present study (see next Sections) and other ones in the literature (see, e.g., [Fienga et al. 2016a]), we can reasonably conclude that the approximation used to calculate the average orbital precessions of Equation (12) and Equation (15) is justified.

4. Constraining the location of PX with the perihelion and the node of Saturn

Batygin & Brown (2016a) did not constrain the true anomaly \(f_X\) of PX; furthermore, in linking its longitude of the ascending node \(\Omega_X\) to the position of the orbital planes of the KBOs used in their analyses, they left room for a certain range of variability in the perturber’s node. Later, Brown & Batygin (2016) explored in more detail the possible parameter space of PX allowing for a certain variability of its other orbital elements as well. Thus, in view also of the still small number of Trans-Neptunian Objects which Batygin & Brown (2016a); Brown & Batygin (2016) built upon their conclusions, we consider our theoretical expressions of Equation (12) and Equation (15), calculated with the values of some selected orbital elements of PX, as functions of just \(x = f_X\) and possibly other (partially) unconstrained orbital elements as independent variables \(x, y, \ldots\), and look for those domains in the \(\{f_X, y, \ldots\}\) hypervolumes which are allowed by

\(^3\)In it, \(t_p\) denotes the time of the passage at pericenter.
4.1. Working with the originally proposed configuration of PX

Let us describe in detail our procedure in the case of the orbital configuration of Table 1 put forth for the first time in Batygin & Brown (2016a); in this case, the unconstrained or partially constrained orbital parameters, assumed as independent variables in our theoretical expressions, are \( x = f_X, y = \Omega_X \), with \( \Omega_X = 113 \pm 13 \) deg (Batygin & Brown 2016a). As a first step, we generate the surfaces representing the graphs of \( \dot{\Omega}_{\text{theo}}(f_X, \Omega_X), \dot{\varpi}_{\text{theo}}(f_X, \Omega_X) \), not shown here, by using Equation (12) and Equation (15) calculated with the values of the orbital elements of Saturn and of PX as listed in Table 1 and for fixed values of the perturber’s mass \( m_X \). Then, by posing \( \dot{\Omega}_{\text{theo}} = \Delta \dot{\Omega}_{\text{obs}}, \dot{\varpi}_{\text{theo}} = \Delta \dot{\varpi}_{\text{obs}} \), we section such plots with horizontal planes corresponding to the maximum and the minimum values of \( \Delta \dot{\Omega}_{\exp}, \Delta \dot{\varpi}_{\exp} \) in Table 4.

The resulting contours, collapsed all together in the \( \{f_X, \Omega_X\} \) plane, delimit two allowed regions \( \mathcal{A}_\sigma, \mathcal{A}_\Omega \) in it, not reproduced here separately for the sake of simplicity. It turns out that each of them allows certain regions in the \( \{f_X, \Omega_X\} \) plane which are, instead, forbidden by the other precession. Finally, we take the intersection \( \mathcal{D} = \mathcal{A}_\sigma \cap \mathcal{A}_\Omega \), which is not empty, in order to further restrict the parameter space of PX in the \( \{f_X, \Omega_X\} \) plane. The results are the shaded regions, representing \( \mathcal{D} \) for \( m_X = 10 - 15 \, m_{\oplus} \), depicted in the upper row of Figure 1. The resulting allowed range for the true anomaly of PX is essentially equal to \( 130 \) deg \( \lesssim f_X \lesssim 240 \) deg for both the values of \( m_X \) considered and for almost the entire domain of variation of \( \Omega_X \) quoted in Table 1 apart from the case \( m_X = 15 \, m_{\oplus} \), 100 deg \( \lesssim \Omega_X \lesssim 110 \) deg when it reduces to 140 deg \( \lesssim f_X \lesssim 200 \) deg. For a bird’s eye view of such constraints, see Figure 8. As far as the position in the sky in terms of the right ascension \( \alpha_X \) and declination \( \delta_X \) is concerned, the bounds of the orbital elements can be translated into corresponding ranges for the Celestial coordinates by means of Equations (19) to (21) and \( \hat{l} \). In particular, we consider \( \alpha_X, \delta_X \) as functions, in
general, of some of the orbital elements $I_X$, $\Omega_X$, $\omega_X$ and of $f_X$, assumed to vary within the ranges both provided by the dynamical simulations by Batygin & Brown (2016a) ($I_X$, $\Omega_X$, $\omega_X$) and our method ($f_X$). Then, we numerically extremize $\alpha_X$, $\delta_X$ and assume such minima and maxima as bounds of the allowed regions in the sky. In this specific case, $I_X$, $\omega_X$ are kept fixed to their values of Table 1, while $\Omega_X$ is allowed to vary within $\Omega_X = 113 \pm 13 \text{ deg}$. It turns out that the left panel in the lower row of Figure 1 displays the allowed portion of Celestial Sphere delimited by $31.1 \text{ deg} \leq \alpha_X \leq 160.2 \text{ deg}$, $-18.9 \text{ deg} \leq \delta_X \leq 32.6 \text{ deg}$ corresponding to the left panel in the upper row of Figure 1; the right panel in the lower row of Figure 1 displaying the region $40.1 \text{ deg} \leq \alpha_X \leq 101.8 \text{ deg}$, $-13.9 \text{ deg} \leq \delta_X \leq 18.4 \text{ deg}$, corresponds to the right panel in the upper row of Figure 1 for $100 \text{ deg} \leq \Omega_X \leq 110 \text{ deg}$.

4.2. Relaxing the orbital configuration of PX

In this Section, we will look at the more recent findings by Brown & Batygin (2016) who explored the parameter space of PX in more depth by allowing for ranges of possible values of its orbital and physical parameters (see Tables 2 to 3). As stressed by Brown & Batygin (2016) themselves, their suggested constraints on the orbital configuration of PX, based on numerical simulations of the evolutionary patterns of certain populations of trans-Neptunian objects under the putative action of the hypothesized distant planet, should be necessarily considered just as preliminary because of the need to cover a substantial part of the possible phase space, the exploratory nature of the simulations themselves, sparsely populated, and the small number of objects actually observed so far.

As described in Section 4.1, also in this Section we will compare our theoretical expressions of Equations (12) to (13) and Equations (15) to (17) for the Kronian orbital precessions with the observational intervals of admissible values quoted in Table 4; then, we will take the intersection of the resulting allowed regions of some selected portions of the parameter space of PX.

4.2.1. Working with partially fixed orientation in space

Let us begin with a fixed spatial orientation of the orbit of PX following the scenario characterized by the relation

$$200 + 30 \left( \frac{m_X}{m_\oplus} \right) \leq \frac{a_X}{\text{au}} \leq 600 + 20 \left( \frac{m_X}{m_\oplus} \right), \quad e_X = 0.75 - \frac{\left[250 + 20 \left( \frac{m_X}{m_\oplus} \right)\right] \text{ au}}{a_X^8}, \quad (23)$$

presented in Section 4 of Brown & Batygin (2016).

The $350 \text{ au} \leq a_X \leq 700 \text{ au}$, $e_X = 0.75 - \left( \frac{350 \text{ au}}{a_X^{-1}} \right)^8$ scenario, which is just a particular case of Equation (23) for $m_X = 5 m_\oplus$, is illustrated in Figure 2. The maximum allowed range
for the true anomaly of PX, i.e. $125 \deg \leq f_X \leq 230 \deg$, occurs for the largest value of its semimajor axis considered, i.e. $a_X = 700 \text{ au}$, independently of $\Omega_X$. It gets much narrower for $a_X = 350 - 400 \text{ au}$ reducing to about $160 \deg \leq f_X \leq 175 - 180 \deg (\Omega_X = 80 \deg)$. $145 \deg \leq f_X \leq 165 - 170 \deg (\Omega_X = 100 \deg)$, $f_X \approx 225 \deg (\Omega_X = 120 \deg)$; a more marked sensitivity to $\Omega_X$ can be noted.

Figure 3 deals with the case $m_X = 10 m_\oplus$, $500 \text{ au} \leq a_X \leq 800 \text{ au}$, $e_X = 0.75 - \left(450 \text{ au} \ a_X^{-1}\right)^8$, another particular case of Equation (23) which is explicitly considered in Section 2 of Brown & Batygin (2016). It can be noticed that the uncertainty in $\Omega_X$ does not affect too much the allowed range of values of $f_X$, which is substantially limited to roughly $130 \deg \leq f_X \leq 230 \deg$ for most of the largest values of either $\Omega_X$ and $a_X$; for $\Omega_X \approx 80 \deg$ and $a_X \approx 500 \text{ au}$, the range for the true anomaly of PX gets narrower amounting to $160 \deg \leq f_X \leq 190 \deg$.

Figure 4 illustrates the other scenario explicitly proposed by Brown & Batygin (2016) in their Section 2 characterized by $m_X = 20 m_\oplus$, $800 \text{ au} \leq a_X \leq 1000 \text{ au}$, $e_X = 0.75 - \left(650 \text{ au} \ a_X^{-1}\right)^8$; it is a further particular case of Equation (23). Now, the dependence from $\Omega_X$ and $a_X$ seems somewhat less pronounced than in Figure 3; the range of allowed values for the PX’s position along its orbits is naively $145 \deg \leq f_X \leq 210 \deg$, reaching $125 \deg \leq f_X \leq 225 \deg$ for $\Omega_X = 120 \deg$.

For the sake of definiteness, in all the three scenarios previously considered we adopted $I_X = 30 \deg$, $\omega_X = 150 \deg$, which are the preferred values in Batygin & Brown (2016) and are compatible with the ranges explored in Brown & Batygin (2016), while we allowed $\Omega_X$ to vary within the range $80 \deg \leq \Omega_X \leq 120 \deg$ preferred by Brown & Batygin (2016); Bailey, Batygin & Brown (2016).

Figure 5 depicts the allowed region $9.1 \deg \leq \alpha_X \leq 165.4 \deg$, $-28.8 \deg \leq \delta_X \leq 39.3 \deg$ onto the Celestial Sphere. It is somewhat representative of all our previous findings since it was obtained by considering the allowed regions for $f_X$ inferred in Figures 2 to 4 and the range of variation for $\Omega_X$ proposed by Brown & Batygin (2016); Bailey, Batygin & Brown (2016). The narrower region $35.4 \deg \leq \alpha_X \leq 82.4 \deg$, $-11.5 \deg \leq \delta_X \leq 13.4 \deg$, corresponding approximately to $80 \deg \leq \Omega_X \leq 100 \deg$, $155 \deg \leq f_X \leq 190 \deg$ in Figures 2 to 4 is depicted as well.

4.2.2. Working with fixed orbital shape and size

In their Section 3, Brown & Batygin (2016) attempt to investigate the possible spatial orientation of the orbit of PX for $m_X = 10 m_\oplus$, $a_X = 700 \text{ au}$, $e_X = 0.6$; they find that the preferred regions for the inclination and the argument of perihelion are $22 \deg \leq I_X \leq 40 \deg$, $120 \deg \leq \omega_X \leq 160 \deg$. Figure 6 explores such a portion of the parameter space of the distant perturber for fixed values of $\Omega_X$ within the previously adopted range i.e. $80 \deg \leq \Omega_X \leq 120 \deg$ Brown & Batygin (2016); Bailey, Batygin & Brown (2016). It can be noticed that the true anomaly of PX ranges from $150 \deg \leq f_X \leq 210 \deg (\Omega_X \approx 110 - 120 \deg$, $\omega_X \approx 120 - 130 \deg)$
to a wider interval as large as about 125 deg \( \lesssim f_X \lesssim 250 \) deg \( (\Omega_X \approx 80 \) deg, \( \omega_X = 120 \) deg). By considering \( \alpha_X, \delta_X \) as functions of \( I_X, \Omega_X, \omega_X, f_X \) within their ranges of variation as per Section 3 of Brown & Batygin (2016) \((I_X, \Omega_X, \omega_X)\) and Figure 5\((f_X)\), it can be inferred an allowed region onto the Celestial Sphere as large as 0 deg \( \lesssim \alpha_X \lesssim 176.8 \) deg, \( -48.4 \) deg \( \lesssim \delta_X \lesssim 48.0 \) deg; it is depicted in Figure 7.

Finally, let us consider the particular orbital configuration of PX selected at the end of Section 3 of Brown & Batygin (2016) as reported in Table 3. It turns out that our method yields an allowed range 130 deg \( \leq f_X \leq 230 \) deg, which is illustrated in Figure 8. It corresponds to a position in the sky in terms of right ascension \( \alpha_X \) and declination \( \delta_X \) delimited by 144.6 deg \( \leq \alpha_X \leq 215.4 \) deg, \( -37.9 \) deg \( \leq \delta_X \leq 37.9 \) deg, as depicted in Figure 9.

### 4.3. Perspectives on the method adopted

Unfortunately, the supplementary node precessions are currently available only for the INPOP10a ephemerides (Fienga et al. 2011); if and when they will be determined by the astronomers also with their most recent ephemerides (see, e.g., Fienga et al. (2016b); Pitjeva & Pitjev (2013)), it will be possible to further strengthen our preliminary constraints on the location of PX and remove the degeneracy in \( \Omega_X \), at least to a certain extent. Unfortunately, no more accurate draconitic extra-precessions have been determined so far with the most recent versions of the INPOP and EPM planetary ephemerides; in this respect, it would also be of the utmost importance if the astronomers will accurately determine the supplementary secular rates of change of more planetary orbital elements since they are all theoretically impacted by a distant perturber, apart from the semimajor axis (Iorio 2012).

### 5. Discussion of other approaches and results in the literature

#### 5.1. General consideration of the method presently adopted

In principle, the approach followed in Section 4 may be criticized because of a certain lack of rigor mainly in view of the need of reprocessing the same set of observations by explicitly modeling the dynamical effect one is looking for and solving for it; otherwise, it could not be excluded that part of the signal of interest, if real, may be somewhat removed, being absorbed in the estimation of, e.g., the planetary initial conditions. As a consequence, the resulting constraints might turn out to be too tight, excluding more or less larger admissible portions of the parameter space. Thus, a complementary dedicated covariance analysis of the available data records by explicitly modeling the dynamical action of PX by the teams routinely engaged in the production of the planetary ephemerides is certainly desirable. On the other hand, it must be stressed that also such a potentially more rigourous approach may have its own drawbacks. Indeed, a
selection of the dynamical effects to be modeled and of the parameters entering them which can be practically estimated is unavoidably always made in real data reduction. Thus, any other sort of unmodeled/mismodeled forces, both standard and exotic, may impact the solved-for parameter(s); the effect of any sort of “Russell teapots” may well creep into the full covariance analysis by somewhat biasing the estimated values one is interested to.

Furthermore, the following considerations are in order. Generally speaking, the opportunistic approach consisting of using data originally processed for different scopes to constrain a wide variety of exotic physical effects arising from several theoretical scenarios aiming to modify the currently known laws of the gravitational interaction at various scales is of common usage in the literature (Nordtvedt 1987; Avalos-Vargas & Ares de Parga 2012; Lin & Wang 2013; Shao & Wex 2013; Xie & Deng 2013; Cheung & Xu 2013; Acedo 2014; Li et al. 2014; Deng & Xie 2014; Capistrano, Roque & Valada 2014; Wilhelm & Dwivedi 2014; Liu et al. 2014; Xie & Deng 2014; Ruggiero 2015; Feldman & Anderson 2015; Acedo 2015; Deng & Xie 2015b,c; Zhao & Xie 2015; Deng & Xie 2015d; Kaminowski 2015; Haris, Gurtug & Mazharimousavi 2015; Deng & Xie 2015a; Ruggiero & Radicella 2015; Hees et al. 2015; Nyambuya 2015; Chicone & Mashhoon 2016; Fienga et al. 2016b; Rodrigues, Mauro & de Almeida 2016; Capistrano, Penagos & Alarcon 2016; Deng & Xie 2016) since, e.g., the early days of general relativity; suffice it to recall that Le Verrier (1859) fit purely Newtonian dynamical and measurement models to the Hermean observations which yielded the celebrated anomalous perihelion precession of Mercury of $42.98 \pm 1$ arcsec cty$^{-1}$ (Einstein 1915; Nobili & Will 1986; Pireaux & Rozelot 2003).

More specifically, a peculiar form of the MOdified Newtonian Dynamics (MOND) theory predicts certain subtle effects on the planetary motions which are able to mimic just those of a far pointlike perturber located in a specific position (Milgrom 2009; Blanchet & Novak 2011). Now, the bounds on the MOND-type parameter inferred analytically in (Iorio 2010) in the same way as done here with older supplementary perihelion advances turned out to be compatible with those later determined in (Hees et al. 2014) by explicitly modeling it in the data reduction procedure of the Cassini telemetry. Furthermore, both Blanchet & Novak (2011) and Fienga et al. (2016b) used a direct comparison of a theoretically predicted orbital percession $\Delta \sigma_{\text{theo}}$ with supplementary precessions $\Delta \sigma_{\text{obs}}$ determined without modeling the PX-type MOND effect to infer constraints on the characteristic parameter at hand. In particular, Fienga et al. (2016b) wrote about the usage of the supplementary perihelion precessions determined with INPOP15a in Table 4: “In terms of comparison to alternative theories of gravitation and in particular to MOND (Ref. 2 [i.e. (Blanchet & Novak 2011)]), the new estimated values [i.e. $\Delta \sigma_{\text{obs}}$] are still competitive for selecting possible MOND functions. Following the Ref. 2 notations, only $\mu_{20(y)}$ is indeed the only possible functions regarding the impact of the quadrupole term $Q_2$ on the advance of planet perihelia.”

Last but not least, another notable case in which both the approaches returned essentially the same outcome is the rejection of the hypothesis that the Pioneer anomaly (Anderson et al. 1998, 2002; Turyshev & Toth 2010) was due to an anomalous extra-acceleration of gravitational origin acting at least on all the major bodies of the Solar System orbiting in the same region
where the alleged anomaly manifested itself (Iorio & Giudice 2006; Tangen 2007; Iorio 2007; Standish 2008, 2010; Pitjeva 2006; Fienga et al. 2009, 2012; Folkner 2009). It came before that its likely mundane origin rooted in standard non-gravitational physics was later demonstrated (Rievers & Lämmerzahl 2011; Turyshchev et al. 2012; Francisco et al. 2012; Modenini & Tortora 2014).

5.2. Comparing the present results for the originally proposed configuration of PX with other ones in the literature

A first step in the complementary direction mentioned in Section 5.1 was meritoriously taken in the recent work by Fienga et al. (2016a). They produced new post-fit residuals $\Delta \rho_X$ of the geocentric range $\rho$ of Saturn (the red curves in their Figure 1) by explicitly including the specific version of PX of Table II (Batygin & Brown 2016a) with $m_X = 10 m_\oplus$ and $\Omega_X = 113$ deg in the dynamical models of the Solar System used to reprocess a decadal record of ranging data from Cassini extending from April 2004 to April 2014 for selected values of $f_X$. Such post-fit residuals were subsequently contrasted to the “nominal” post-fit ones $\Delta \rho_0$ obtained by reducing the same data set without modeling PX at all; the set of the estimated parameters is the same for both the residuals, apart from those of the Moon which were not included in the solution for $\Delta \rho_X$. As an outcome, certain regions of admissible values for $f_X$ were inferred (85 deg $\lesssim f_X \lesssim 235$ deg and 260 deg $\lesssim f_X \lesssim 295$ deg) along with a claimed most probable interval of values for it amounting to $f_X = 117.8^{+11}_{-10}$ deg. The results by Fienga et al. (2016a) can be compared with our findings in Section 4.1, Figure 1 from which it turns out that our allowed region for the true anomaly of PX is 130 deg $\lesssim f_X \lesssim 240$ deg. It overlaps with the largest allowed region claimed by Fienga et al. (2016a) to a large extent; on the other hand, their claimed most probable interval of values is incompatible with our bounds. Cfr. the upper panel of our Figure 10 extracted from Figure 1 with Figure 6 of Fienga et al. (2016a), adapted in the lower panel of Figure 10 in order to display just the allowed regions inferred from the analysis of the existing 2004-2014 Cassini data.

As far as the range-based study by Holman & Payne (2016b) is concerned, they looked at the configuration for PX originally proposed by Batygin & Brown (2016a) with $\Omega_X = 113$ deg in their Section 4 and Figure 3. Holman & Payne (2016b) first claimed that they were able to reproduce the results by Fienga et al. (2016a). Then, after having adopted a different statistical criterion and having kept also outlying data points, Holman & Payne (2016b) stated that there would be “significant room for further investigation because excluding outlying data points and using a standard $\chi^2$ statistic allow for more nuanced model evaluation”. Nonetheless, no explicit new intervals of allowed values for $f_X$ were provided by Holman & Payne (2016b); a mere visual inspection of Figure 3 of Holman & Payne (2016b) does not allow to infer them in a clear way.

The parameterization used by Fienga et al. (2016a) for $f_X$ is different from ours here since they assumed $-180$ deg $\leq f_X \leq 180$ deg.
5.3. Comparing our results for different orbital and physical configurations with other studies in the literature

In Figure 10 of their Section 4, Brown & Batygin (2016), using all constraints on the orbital and physical parameters of the hypothesized distant planet arising from their dynamical simulations of selected populations of KBOs, predict its possible orbital path across the sky. The result is a continuous, sinusoidal strip in the \(\{\alpha_X, \delta_X\}\) plane limited by \(-40\ \text{deg} \leq \delta_X \leq 40\ \text{deg}\); no intervals in the \(\alpha_X\) axis seem to be forbidden. It is neither straightforward nor easy to make a direct comparison with our results for the allowed regions onto the Celestial Sphere in Section 4 since quantitative details about the values of the orbital and physical parameters of PX used are missing in Brown & Batygin (2016); furthermore, only a visual inspection of their Figure 10 is possible. Nonetheless, let us try a comparison with, say, our Figures 1 and 9, both corresponding to \(a_X = 700\ \text{au}\). From the second panel from the top of Figure 10 of Brown & Batygin (2016), it seems that such a value of the perturber’s semimajor axis is possible only for roughly \(0\ \text{deg} \lesssim \alpha_X \lesssim 135 - 140\ \text{deg}\). In turn, the first panel from the top of Figure 10 of Brown & Batygin (2016) tells us that the corresponding range in declination is approximately \(-40\ \text{deg} \leq \delta_X \leq 40\ \text{deg}\); actually, a range of values for \(\delta_X\) corresponds to each value of \(\alpha_X\).

Unfortunately, it is impossible to associate specific values of both the mass of PX and its other orbital parameters to such naive guesses based only on looking at Figure 10 of Brown & Batygin (2016). Now, depending on both \(m_X\) and \(\Omega_X\), our Figure 1 and 9 both corresponding to \(a_X = 700\ \text{au}\). From the second panel from the the top of Figure 10 of Brown & Batygin (2016), it seems that such a value of the perturber’s semimajor axis is possible only for roughly \(0\ \text{deg} \lesssim \alpha_X \lesssim 135 - 140\ \text{deg}\). In turn, the first panel from the top of Figure 10 of Brown & Batygin (2016) tells us that the corresponding range in declination is approximately \(-40\ \text{deg} \leq \delta_X \leq 40\ \text{deg}\); actually, a range of values for \(\delta_X\) corresponds to each value of \(\alpha_X\).

In their Section 5.2, Holman & Payne (2016b) adopted a Markov Chain Monte Carlo (MCMC) approach to generate a distribution of realizations of PX with specific masses and orbital elements. They, then, used them to generate associated preferred locations for PX from Cassini range data alone in the \(\{\alpha_X, \delta_X\}\) plane, depicted in their Figure 6. As a result, they obtained two narrow bands with curvilinear contours essentially perpendicular to the orbit of Saturn. From a visual inspection of Figure 6 of Holman & Payne (2016b), it seems that they are approximately centered in \(\alpha_X \approx 30\ \text{deg}\) and \(\alpha_X \approx 200\ \text{deg}\), being as large as about \(-60\ \text{deg} \leq \delta_X \leq 60\ \text{deg}\) in declination. Then, Holman & Payne (2016b) considered the intersections of such allowed regions with the swath of possible positions in the sky of Figure 10 by Brown & Batygin (2016) finding two much narrower domains quantitatively characterized in Table 1 of Holman & Payne (2016b). It contains the median and 1\(\sigma\) ranges for the best-fit quantities arising from the combined MCMC analysis of the Cassini data by Holman & Payne (2016b) with the dynamical constraints from Brown & Batygin (2016). While one of such two regions, corresponding to \(m_X < 5\ \text{m}_\oplus\) and denoted as Zone-1, has to be discarded, the other one, characterized, among other things, by \(142\ \text{deg} \lesssim f_X \lesssim 164\ \text{deg}\) and called Zone-2, is considered by Holman & Payne (2016b) as the preferred region on the sky to find PX. We reproduce part of it in Table 5.

\footcite{Holman & Payne (2016b)} used the mean anomaly \(M\) as positional angle along the orbit of
that such an interval of values for \( f_X \) is compatible with our bounds obtained in Section 4 for many of the orbital and physical scenarios of PX, retrieved from Batygin & Brown (2016a); Brown & Batygin (2016), which fall within the ranges reported in Table 1 of Holman & Payne (2016b) for Zone-2. Conversely, it can be demonstrated that, if we apply our approach of Section 4 based on the node and the perihelion precessions of Saturn to the ranges of parameters of PX quoted in the Zone-2 of Table 1 of Holman & Payne (2016b), it is possible to obtain just \( 142 \text{ deg} \lesssim f_X \lesssim 164 \text{ deg} \). As far as the position in the sky is concerned, it should be noted that if we apply our method, described in Section 4.1, to extract the maximum and the minimum values of \( \alpha_X, \delta_X \) from suitable variations of the orbital elements of PX, the allowed region in the sky corresponding to the range of values reported for the preferred region in Table 1 of Holman & Payne (2016b), is \( 3 \text{ deg} \lesssim \alpha_X \lesssim 78 \text{ deg}, -38 \text{ deg} \lesssim \delta_X \lesssim 5.3 \text{ deg} \), which is larger than \( \alpha_X = 39.5^{+5.5}_{-5.3} \text{ deg}, \delta_X = -15.4^{+6.7}_{-6.6} \text{ deg} \) quoted by Holman & Payne (2016b) in their Table 1.

6. Constraining the mass of PX

In this Section, we address the problem of attempting to constrain \( m_X \) treating it as a free parameter, without any a priori limitations on its possible values. To this aim, we will adopt the same strategy followed in Section 4 in order to have preliminary bounds based solely on the orbital dynamics of Saturn. As such, we will treat \( m_X \) as one of the independent variables of Equation (12) and Equation (15); as far as the orbital configuration of PX is concerned, we will explore the relaxed parameter space of Table 2. Figures 11 to 12 show the allowed regions in the \( \{ f_X, m_X \} \) plane for given values of the orbital elements of PX chosen within their range of variations according to Table 2. It can be noted that, while there is room practically along the entire orbit for masses as little as \( m_X \approx 1 m_\oplus \) or so, larger masses can be found, as expected, only in increasingly limited portions of the orbit, mainly concentrated around the aphelion. Moreover, the resulting upper limits for the admissible values of \( m_X \), as provided by the Kronian orbital precessions, are often much greater than 20 \( m_\oplus \) envisaged by Brown & Batygin (2016). For example, in the case of the preferred orbital configuration of Table 1 with \( \Omega_X = 113 \text{ deg} \), it turns out from Figure 13 that masses larger than 20 \( m_\oplus \) are, indeed, quite possible, with a maximum of about 36 \( m_\oplus \) confined at \( f_X \approx 155 \text{ deg} \). A strong dependence on \( \Omega_X \) is observed, with \( m_X^{\text{max}} = 92 m_\oplus \) at about \( f_X \approx 178 \text{ deg} \) for \( \Omega_X = 80 \text{ deg} \).

Finally, it must be stressed that the aforementioned strategy is able to provide only upper limits on \( m_X \). No physically meaningful lower limits \( m_X^{\text{min}} \), with \( m_X^{\text{min}} > 0 \), can, instead, be obtained because of the error bars in the orbital precessions of Table 4 which, in principle, would allow also negative values for \( m_X \). In other words, the allowed regions in Figures 11 to 13 may well extend down to negative values of \( m_X \).

PX. As such, the range for \( f_X \) quoted here is calculated via the Kepler equation for \( e_X = 0.5 \).
7. The potential impact on New Horizons: a preliminary sensitivity analysis

After having encountered Pluto in the mid of July 2015, the spacecraft New Horizons (Stern 2008) is currently en route to the object 2014 MU$_{69}$ of the Kuiper Belt, at about 43 au, to be reached in 2019. New Horizons is endowed with a radio science apparatus, named REX (Tyler et al. 2008), which should allow to determine the spacecraft geocentric range $\rho$ with an accuracy better than $\sigma_{\rho} = 10$ m over 6 years after 2015, i.e. at geocentric distances to beyond 50 au (Fountain et al. 2008).

Following an idea put forth in Iorio (2013), its range residuals may, in principle, be used to put tighter constraints on the admissible locations of PX in the near–mid future; later, Buscaino et al. (2015) proposed a dedicated deep-space mission aimed to test the currently accepted gravitational laws up to 100 au. For the sake of simplicity, we will investigate only the preferred orbital configuration by Batygin & Brown (2016a). Figures 14 to 15 depict the simulated range perturbation induced by a hypothetical distant perturber with the physical and orbital features of Table 1 within approximately the ranges of admissible values for $f_X$, $\Omega_X$ set by Figure 1. Incidentally, the observable probed here, i.e. the Earth–spacecraft distance, is of similar nature as the one used by Fienga et al. (2016a) with Cassini. It can be noted that the peak-to-peak amplitudes range from about $\approx 50 − 60$ m up to $\approx 150 − 300$ m depending on the orbital geometry of PX. In obtaining each curve of Figures 14 to 15 we simultaneously integrated the barycentric equations of motion of all of the currently known major bodies of the Solar System in Cartesian rectangular coordinates over a time span 3 years long starting from February 1, 2016 with and without PX. The dynamical accelerations modeled in both the integrations include the general theory of relativity to the first post-Newtonian level, and all the major known Newtonian effects such as the Sun’s oblateness, pointlike mutual perturbations by the eight planets and the three largest asteroids, two massive rings accounting for the minor asteroids and the Kuiper Belt’s objects. Then, from the so–obtained solutions of the perturbed and unperturbed equations of motion, we numerically produced differential time series $\Delta \rho (t)$ of the Earth–spacecraft range $\rho (t)$. The amplitudes of such simulated signals can be compared to $\sigma_{\rho}$ in order to gain insight about the potential ability of New Horizons to constrain/detect its existence in future. It turns out that, even over a limited time span as that required to reach 2014 MU$_{69}$, the expected range signatures due to the hypothesized PX could be as large as some hundreds of meters. On the other hand, caution is advised because of the orbital maneuvers, not taken into account in the present tentative simulations, which will require accurate modeling. Moreover, the present investigation should be considered just as a preliminary sensitivity analysis based on the expected precision of the probe’s measurements: actual overall accuracy will be finally determined by several sources of systematic uncertainties like, e.g., the heat dissipation from the Radioisotope Thermoelectric Generator (RTG) and the ability in accurately modeling the orbital maneuvers. As such, by no means, it is meant to replace a full covariance study based on extensive simulations of the ranging data from New Horizons and their reduction with accurate models including also PX itself, which is outside the scopes of this paper. Nonetheless, the possibility of using the telemetry of New Horizons seems appealing, and would deserve further, more detailed and dedicated studies which,
hopefully, may be prompted by the present one; as a potentially interesting topic for further investigations, we mentioned the possibility of jointly using the latest years of Cassini data as well to achieve a better fit.

8. Summary and conclusions

Combining the recent experimental determinations of the supplementary perihelion and node rates of Saturn, quoted in our Table 4 with our analytical formulas of Equations (12) to (13) and Equations (15) to (17) for the theoretical apsidal and draconitic precessions induced by the putative new planet of the Solar System under consideration allows us to tentatively constrain its position along its orbit for selected scenarios of such a hypothesized body characterized by given values of its mass and its orbital elements. We stress that, since its gravitational tug on the known bodies of the Solar System was neither modelled nor estimated in the ephemerides which the extra-precessions of Saturn used by us come from, our analyses should be deemed as proof-of-principle investigations to encourage future, more rigorous analyses. The present study, which should be supplemented by dedicated data reductions by the international teams producing the planetary ephemerides in which the gravitational action of PX should be explicitly modeled, can be useful in either further refining the scenarios describing the shepherding action on the KBOs by the hypothesized trans-Neptunian super-Earth and better addressing further observational campaigns. In this respect, the attempt by Fienga et al. (2016a) is a first valuable step in the right direction. Nonetheless, the preliminary bounds resulting from our analysis are reasonable and, to a non-negligible extent, in agreement with other studies making use of different observables.

As far as the originally proposed configuration of PX (Batygin & Brown 2016a), displayed in our Table 1 is concerned, a direct and meaningful comparison with the results by Fienga et al. (2016a) is possible. Indeed, they too considered such a specific scenario by choosing the central value of the perturber’s node within the range of variation suggested in the literature for it. Fienga et al. (2016a), who produced post-fit residuals of the Earth-Saturn range in a dedicated data reduction of real range measurements covering the decade 2004-2014 by explicitly modeling PX, obtained disjointed allowed regions for it. They are 85 deg \( \leq f_X \leq 235 \) deg, which includes also their claimed most probable interval of values \( f_X = 117.8^{+11}_{-10} \) deg, and 260 deg \( \leq f_X \leq 295 \) deg. For the same choice of the value of the node of the originally proposed model of PX, we obtained only one continuous allowed region given by 130 deg \( \leq f_X \leq 240 \) deg, as depicted by our Figure 1. It is almost entirely included in the largest allowed region by Fienga et al. (2016a), whose most probable range is, on the other hand, excluded by us: our Figure 10 clearly illustrates this fact. Instead, the location of the orbital plane in space of the hypothesized distant perturber at hand, assumed as an unconstrained parameter within its admitted range of variation in its earliest

\footnote{I thank H. Beust for such a suggestion.}
scenario, is left substantially undetermined by our analysis. At present, the current accuracy level in planetary ephemerides does not seem to allow to remove the degeneracy in the node of PX. Future improvements, which should come from the analysis of more radiometric data from Cassini, doomed to fatally plunge into Saturn’s atmosphere in late 2017, may break it, at least to a certain extent. To this aim, we remark that a future determination of the supplementary precessions of further orbital elements of Saturn by the astronomers producing the planetary ephemerides would be a quite valuable and highly desirable step to infer tighter constraints on both the location of PX along its orbit and of its orbital plane in space.

The investigation of the relaxed versions by Brown & Batygin (2016) of the preferred orbital configuration of PX (Batygin & Brown 2016a), reproduced in our Tables 2 to 3, makes more difficult to present our results in an unitary way and comparing them with other findings in the literature. A common feature of all our analyses performed by sampling the enlarged parameter space of the putative new planet and shown by Figures 2 to 9 is that the simultaneous use of both the node and the perihelion precessions of Saturn allows us to obtain always single continuous areas or volumes of permitted parameters of PX by allowing to discard smaller disjointed regions which the use of only one Kronian orbital precession at a time would force us to keep. Moreover, the resulting intervals of permitted values of the true anomaly of PX are always essentially centered on its aphelion, spanning roughly from \( \Delta f_X \approx 30 \) deg for certain specific values characterizing some of the boundaries of the perturber’s parameter space up to about \( \Delta f_X \approx 100 – 125 \) deg for most of the remaining domain. Importantly, our strategy is able to reproduce the range \( 142 \, \text{deg} \lesssim f_X \lesssim 164 \, \text{deg} \) corresponding to the relatively restricted portion of the parameter space of PX, reproduced in our Table 5, picked up in Holman & Payne (2016b) by comparing their own allowed regions with the continuous sinusoidal strip by Brown & Batygin (2016) in the plane of the sky.

We also attempted to put constraints on the upper limits of the mass of PX for given orbital configurations retrieved from Batygin & Brown (2016a), Brown & Batygin (2016) by treating it as a free, apriori unconstrained parameter. Our Figures 11 to 13 show that the nodal and apsidal precessions of Saturn actually leave room for larger values of \( m_X \) than the upper limit of 20 \( m_\oplus \) suggested by Brown & Batygin (2016), but they are confined in quite small orbital portions nearly around the aphelion. In particular, in the case of the preferred orbital geometry by Batygin & Brown (2016a), the largest allowed value for the mass of PX is \( m_X \approx 36 \, m_\oplus \) which could stay only at about \( f_X \approx 155 \) deg if \( \Omega_X = 113 \) deg. Instead, if \( \Omega_X = 80 \) deg, a mass as large as \( m_X \approx 92 \, m_\oplus \) at \( f_X \approx 178 \) deg is still admissible. Since the supplementary orbital precessions of Saturn are statistically compatible with zero, our strategy is not able to provide physically meaningful lower limits on \( m_X \), being unphysical negative values of \( m_X \) admissible.

Finally, we mention also the potentially appealing opportunity of using in the mid future the precise telemetry of the ongoing New Horizons mission, which is currently traveling at about 35 au and whose range would be perturbed up to some hundreds of meters by PX, or, hopefully, of some missions proposed to test the currently accepted laws of the gravitational interaction in the far reaches of the Solar System, at about 100 au. Caution is, however, advised since it remains to
be seen whether it will be actually possible to deal with smooth orbital arcs long enough for New Horizons by effectively modeling the non-gravitational perturbations affecting it and its orbital maneuvers. Perhaps, also the latest data from Cassini might be jointly used to improve the fit.

A. Tables and Figures

Table 1: Nominal orbital elements originally proposed by Batygin & Brown (2016a) for a distant pointlike perturber PX of mass $m_X = 10 m_\oplus$ in order to explain reasonably well the observed clustering of either the apsidal and nodal lines of the orbits of some of the known distant KBOs. The values for the inclination $I_X$ and the argument of perihelion $\omega_X$ are referred to the ecliptic. The values for the semimajor axis $a_X$ and the eccentricity $e_X$ proposed by Batygin & Brown (2016a) correspond to a perihelion distance $q_X = 280$ au and an aphelion distance $Q_X = 1120$ au. As far as the longitude of the ascending node of PX is concerned, it seems that Batygin & Brown (2016a) favor the range $\Omega_X = 113 \pm 13$ deg, based on the orientation of the orbital planes of the KBOs considered.

| $a_X$ (au) | $e_X$ | $I_X$ (deg) | $\omega_X$ (deg) |
|------------|-------|-------------|-------------------|
| 700        | 0.6   | 30          | 150               |
Table 2: Enlarged parameter space of PX, valid for $5 \, m_\oplus \leq m_X \leq 20 \, m_\oplus$, as per Section 4 of Brown & Batygin (2016) and Section 3 of Bailey, Batygin & Brown (2016). It must be remarked that, in their Section 2, Brown & Batygin (2016) seemingly used the displayed formulas for $a_X$, $e_X$ with $m_X = 10, 20 \, m_\oplus$ by keeping the inclination and the argument of perihelion fixed to $I_X = 30^\circ$, $\omega_X = 150^\circ$. Instead, in their Section 3, Brown & Batygin (2016) adopted the displayed ranges for $I_X$, $\omega_X$ with the fixed values $m_X = 10 \, m_\oplus$, $a_X = 700 \, \text{au}$, $e_X = 0.6$. For another PX scenario proposed by Brown & Batygin (2016), see Table 3.

| $a_X$ (au) | $e_X$ | $I_X$ (deg) | $\Omega_X$ (deg) | $\omega_X$ (deg) |
|-----------|-------|-------------|-----------------|-----------------|
| $[200 + 30 \, \frac{m_X}{m_\oplus}, \, 600 + 20 \, \frac{m_X}{m_\oplus}]$ | $0.75 - \left(\frac{250 + 20 \, \frac{m_X}{m_\oplus}}{a_X}\right)^{0.8}$ | $[22, \, 40]$ | $[80, \, 120]$ | $[120, \, 160]$ |
Table 3: Orbital and physical parameters of PX as proposed at the end of Section 3 of Brown & Batygin (2016) in the framework of the final full three-dimensional simulation with a large number of particles with randomly chosen starting angles.

| $m_X$ ($m_\oplus$) | $a_X$ (au) | $e_X$ | $I_X$ (deg) | $\omega_X$ (deg) | $\Omega_X$ (deg) |
|---------------------|------------|-------|-------------|------------------|------------------|
| 10                  | 700        | 0.6   | 30          | 0                | 0                |
Table 4: Most recent determinations $\Delta \dot{\varpi}_{\text{obs}}$, $\Delta \dot{\Omega}_{\text{obs}}$ of the supplementary secular precessions of the longitudes of the perihelion $\varpi$ and the ascending node $\Omega$ of Saturn obtained with the EPM2011 (Pitjeva & Pitjev 2013), INPOP10a (Fienga et al. 2011) and INPOP15a (Fienga et al. 2015, 2016b) ephemerides by processing data records spanning about $\Delta t = 100$ yr which include also accurate radiometric measurements from the Cassini spacecraft. The dynamical action of the putative distant object hypothesized by Batygin & Brown (2016a) was not modeled in any of the ephemerides used. The units are milliarcseconds per century (mas cty$^{-1}$). In principle, $\Delta \dot{\varpi}_{\text{obs}}$, $\Delta \dot{\Omega}_{\text{obs}}$ account for any unmodelled/mismodelled dynamical effects in the ephemerides used for their determination.

|                  | EPM2011 (Pitjeva & Pitjev 2013) | INPOP10a (Fienga et al. 2011) | INPOP15a (Fienga et al. 2016b) |
|------------------|---------------------------------|-------------------------------|---------------------------------|
| $\Delta \dot{\varpi}_{\text{obs}}$ | $-0.32 \pm 0.47$               | $0.15 \pm 0.65$               | $0.625 \pm 2.6$                |
| $\Delta \dot{\Omega}_{\text{obs}}$ | $-$                             | $-0.1 \pm 0.4$               | $-$                             |

Table 5: Selected physical and orbital parameters of PX from Zone-2 of Table 1 in Holman & Payne (2016b). Here, $\mathcal{M}_X$ denotes the mean anomaly.

| $m_X$ ($m_\oplus$) | $a_X$ (au) | $e_X$ | $I_X$ (deg) | $\Omega_X$ (deg) | $\omega_X$ (deg) | $\mathcal{M}_X$ (deg) |
|--------------------|------------|-------|-------------|-------------------|------------------|---------------------|
| $17.7^{+8.4}_{-9.1}$ | $478.7^{+0.5}_{-0.1}$ | $0.5^{+0.1}_{-0.1}$ | $32.7^{+5.3}_{-6.9}$ | $97.8^{+14.5}_{-14.7}$ | $138.7^{+14.3}_{-13.0}$ | $117.2^{+25.7}_{-25.0}$ |
Fig. 1.— Upper row: intersections $D = \mathcal{A}_m \cap \mathcal{A}_\Omega$ of the allowed regions in the $\{ f_X, \Omega_X \}$ plane determined by the INPOP10a ephemerides (Fienga et al. 2011) through a comparison of Equations (12) to (13) and Equations (15) to (17), computed with Equations (19) to (21) and the nominal orbital values in Table 1 (Left: $m_X = 10 \ m_\oplus$. Right: $m_X = 15 \ m_\oplus$), with $\Delta \Omega_{\text{obs}}, \Delta \sigma_{\text{obs}}$ quoted in Table 4. As per the variability of $\Omega_X$, we restrict ourselves to the interval of values which seem to be favored in Batygin & Brown (2016a), i.e. $\Omega_X = 113 \pm 13$ deg. The uncertainty in $\Omega_X$ does not affect too much the allowed ranges for $f_X$, especially for $m_X = 10 \ m_\oplus$. In this case, it is basically $130 \deg \lesssim f_X \lesssim 240 \deg$. For $m_X = 15 \ m_\oplus$, the permitted domain of $f_X$ is essentially equal to that of $m_X = 10 \ m_\oplus$ when $110 \deg \lesssim \Omega_X \lesssim 126 \deg$. Instead, for $\Omega_X = 100 \deg$, it shrinks down to $140 \deg \lesssim f_X \lesssim 200 \deg$. Lower row: corresponding allowed regions onto the Celestial Sphere; the left panel depicts the area $31.1 \deg \lesssim \alpha_X \lesssim 160.2 \deg, -18.9 \deg \lesssim \delta_X \lesssim 32.6 \deg$. The right panel displays the region $40.1 \deg \lesssim \alpha_X \lesssim 101.8 \deg, -13.9 \deg \lesssim \delta_X \lesssim 18.4 \deg$ corresponding to the case $m_X = 15 \ m_\oplus, 100 \deg \lesssim \Omega_X \lesssim 110 \deg$. The $\{x, y\}$ plane is the Celestial Equator, while the $z$ axis points towards the Celestial North Pole.
Fig. 2.— Allowed regions in the parameter space of PX as determined by the INPOP10a ephemerides (Fienga et al. 2011) through a comparison of Equations (12) to (13) and Equations (15) to (17), computed with Equations (19) to (21) and the physical and orbital parameters of PX for the $m_X = 5 m_\oplus$, $350 \text{ au} \leq a_X \leq 700 \text{ au}$, $e_X = 0.75 - (350 \text{ au} \ a_X)^8$ scenario, which is just a particular case of Equation (23) and Table 2. While the inclination and the argument of perihelion are kept fixed to $I_X = 30 \text{ deg}$, $\omega_X = 150 \text{ deg}$ (Batygin & Brown 2016a; Brown & Batygin 2016), the longitude of ascending node is allowed to vary within $80 \text{ deg} \leq \Omega_X \leq 120 \text{ deg}$ (Brown & Batygin 2016; Bailey, Batygin & Brown 2016). In the left upper corner, the allowed region in the $\{a_X, f_X, \Omega_X\}$ volume inferred from the simultaneous overlapping of the allowed regions by both the node and the perihelion of Saturn is depicted. The other pictures represent selected sections of it in the $\{a_X, f_X\}$ plane obtained for fixed values of $\Omega_X$. The widest allowed range of allowed values for the true anomaly of PX is $125 \text{ deg} \leq f_X \leq 230 \text{ deg}$; it is almost independent of $\Omega_X$ and occurs for $a_X = 700 \text{ au}$. A stronger dependence on $\Omega_X$ can be observed for lower values of $a_X$. 
Fig. 3.— Allowed regions in the parameter space of PX as determined by the INPOP10a ephemerides (Fienga et al. 2011) through a comparison of Equations (12) to (13) and Equations (15) to (17), computed with Equations (19) to (21) and the physical and orbital parameters of PX as for the $m_X = 10~m_\oplus$, $500~\text{au} \leq a_X \leq 800~\text{au}$, $e_X = 0.75 - (450~\text{au}/a_X)^{1/8}$ scenario (it is a particular case for $m_X = 10~m_\oplus$ of Equation (23) in Section 2 of Brown & Batygin (2016). While the inclination and the argument of perihelion are kept fixed to $I_X = 30$ deg, $\omega_X = 150$ deg (Batygin & Brown 2016a; Brown & Batygin 2016), the longitude of ascending node is allowed to vary within $80$ deg $\leq \Omega_X \leq 120$ deg (Brown & Batygin 2016; Bailey, Batygin & Brown 2016). In the left upper corner, the allowed region in the $\{a_X, f_X, \Omega_X\}$ volume inferred from the simultaneous overlapping of the allowed regions by both the node and the perihelion of Saturn is depicted. The other pictures represent selected sections of it in the $\{a_X, f_X\}$ plane obtained for given values of $\Omega_X$. The uncertainty in $\Omega_X$ does not substantially affect the allowed range of values of $f_X$, which is roughly confined in the range $130$ deg $\leq f_X \leq 230$ deg. It reduces to roughly $160$ deg $\leq f_X \leq 190$ deg for $\Omega_X \approx 80$ deg, $a_X \approx 500$ au.
Fig. 4.— Allowed regions in the parameter space of PX as determined by the INPOP10a ephemerides (Fienga et al. 2011) through a comparison of Equations (12) to (13) and Equations (15) to (17), computed with Equations (19) to (21) and the physical and orbital parameters of PX as for the $m_X = 20 m_\oplus$, $800 \text{ au} \leq a_X \leq 1000 \text{ au}$, $e_X = 0.75 - \left(\frac{650 \text{ au}}{a_X}\right)^{0.8}$ (it is a particular case for $m_X = 20 m_\oplus$ of Equation (23) in Section 2 of Brown & Batygin (2016). While the inclination and the argument of perihelion are kept fixed to $I_X = 30$ deg, $\omega_X = 150$ deg (Batygin & Brown 2016a; Brown & Batygin 2016), the longitude of ascending node is allowed to vary within $80$ deg $\leq \Omega_X \leq 120$ deg (Brown & Batygin 2016; Bailey, Batygin & Brown 2016). In the left upper corner, the allowed region in the $\{a_X, f_X, \Omega_X\}$ volume inferred from the simultaneous overlapping of the allowed regions by both the node and the perihelion of Saturn is depicted. The other pictures represent selected sections of it in the $\{a_X, f_X\}$ plane obtained for given values of $\Omega_X$. The uncertainty in $\Omega_X$ does not substantially affect the allowed range of values of $f_X$, which is roughly confined in the range $125$ deg $\leq f_X \leq 250$ deg. For $\Omega_X \approx 80$ deg, $a_X \approx 800$ au, it slightly reduces down to about $150$ deg $\leq f_X \leq 210$ deg.
Fig. 5.— Left panel: allowed region $9.1 \text{ deg} \leq \alpha_X \leq 165.4 \text{ deg}, \quad -28.8 \text{ deg} \leq \delta_X \leq 39.3 \text{ deg}$ onto the Celestial Sphere. It yields an overall representation of most of the bounds in Figure 2 to 4. Right panel: more restricted area $35.4 \text{ deg} \leq \alpha_X \leq 82.4 \text{ deg}, \quad -11.5 \text{ deg} \leq \delta_X \leq 13.4 \text{ deg}$ corresponding to $80 \text{ deg} \leq \Omega_X \leq 100 \text{ deg}, \quad 155 \text{ deg} \leq f_X \leq 190 \text{ deg}$ in Figures 2 to 4. The $\{x, y\}$ plane is the Celestial Equator, while the $z$ axis points towards the Celestial North Pole.
Fig. 6.— Allowed regions in the \( \{ I_X, f_X, \omega_X \} \) volume for PX as determined by the INPOP10a ephemerides (Fienga et al. 2011) through a comparison of Equations (12) to (13) and Equations (15) to (17), computed with Equations (19) to (21) and the physical and orbital parameters of PX as in Section 3 of Brown & Batygin (2016) for the \( m_X = 10 \, m_\oplus, a_X = 700 \, \text{au}, e_X = 0.6, \, \Omega_X = 80 \, \text{deg} \) scenario, i.e. \( 22 \, \text{deg} \leq I_X \leq 40 \, \text{deg}, \, 120 \, \text{deg} \leq \omega_X \leq 160 \, \text{deg} \). The longitude of ascending node \( \Omega_X \) is kept fixed to some values within \( 80 \, \text{deg} \leq \Omega_X \leq 120 \, \text{deg} \) (Brown & Batygin 2016; Bailey, Batygin & Brown 2016). It must be recalled that \( I_X = 30 \, \text{deg}, \, \omega_X = 150 \, \text{deg} \) are the favored values, as per Figure 7 of Brown & Batygin (2016). The maximum allowed region for the true anomaly of PX ranges from a minimum of \( 150 \, \text{deg} \leq f_X \leq 210 \, \text{deg} \) to a maximum of \( 125 \, \text{deg} \leq f_X \leq 250 \, \text{deg} \).
Fig. 7.— Globally allowed region in the sky, characterized by $0 \deg \lesssim \alpha_X \lesssim 176.8\,\deg$, $-48.4\,\deg \lesssim \delta_X \lesssim 48.0\,\deg$, according to the allowed values for $f_X$ of Figure 6 and the ranges of variation for $I_X,$ $\Omega_X,$ $\omega_X$ as per Section 3 of Brown & Batygin (2016). The $\{x, y\}$ plane is the Celestial Equator, while the $z$ axis points towards the Celestial North Pole.
Fig. 8.— Upper panel: allowed region (shaded area delimited by $130 \, \text{deg} \leq f_X \leq 230 \, \text{deg}$) for $P_X$ as determined by the INPOP10a ephemerides (Fienga et al. 2011) through a comparison of Equations (12) to (13) and Equations (15) to (17), computed with Equations (19) to (21) and the physical and orbital parameters of $P_X$ as in Table 3. In terms of right ascension $\alpha_X$ and declination $\delta_X$, it corresponds to $144.6 \, \text{deg} \leq \alpha_X \leq 215.4 \, \text{deg}$, $-37.9 \, \text{deg} \leq \delta_X \leq 37.9 \, \text{deg}$; see Figure 9. The aforementioned range for $f_X$ substantially holds also for the different orbital configuration of $P_X$ in Table 1, cfr. the left upper panel of Figure 1. Lower panel: allowed region for the $m_X = 15 \, m_\oplus$, $\Omega_X = 100 \, \text{deg}$ case of the right upper panel of Figure 1.
Fig. 9.— Allowed portion of the Celestial Sphere, determined by $144.6 \, \text{deg} \leq \alpha_X \leq 215.4 \, \text{deg}$, $-37.9 \, \text{deg} \leq \delta_X \leq 37.9 \, \text{deg}$, for the physical and orbital configuration of PX of Table 3 and the upper panel of Figure 8. The \{x, y\} plane is the Celestial Equator, while the z axis points towards the Celestial North Pole.
Fig. 10.— Upper panel: allowed region for Table 1 extracted from our Figure 1 for $m_X = 10 m_p$, $\Omega_X = 113 \text{ deg}$ (Batygin & Brown 2016a). Lower panel: allowed regions as per Fienga et al. (2016a) for the same scenario of PX. According to Fienga et al. (2016a), the allowed regions are $85 \deg \lesssim f_X \lesssim 235 \deg$, which includes also the claimed most probable interval of values $108 \deg \lesssim f_X \lesssim 129 \deg$, here depicted as the darker shaded area, and the disjointed area $260 \deg \lesssim f_X \lesssim 295 \deg$. 

$m_Y = 10 m_p$, $a_Y = 700 \text{ au}$, $e_Y = 0.6$, $I_Y = 30 \deg$, $\Omega_Y = 113 \deg$, $\omega_Y = 150 \deg$
Fig. 11.— Dynamical constraints on the mass of PX inferred from the orbital precessions of Saturn as in Section 4. No apriori limitations on the values of $m_X$ were applied. The range of variations of the Euler-type angular orbital parameters $I_X$, $\Omega_X$, $\omega_X$ of PX were taken from the relaxed parameter space of Table 2.
Fig. 12.— Dynamical constraints on the mass of PX inferred from the orbital precessions of Saturn as in Section 4. No a priori limitations on the values of $m_X$ were applied. The inclination of the orbit of PX in space, its orientation in its plane and its shape were taken from Table 1 and $\Omega_X = 113$ deg.
Fig. 13.— Dynamical constraints on the mass of PX inferred from the orbital precessions of Saturn as in Section 4. No apriori limitations on the values of $m_X$ were applied. The orbital configuration of Table 1, with $80 \, \text{deg} \leq \Omega_X \leq 120 \, \text{deg}$, is adopted. Values of $m_X$ even much larger than 20 $m_\oplus$ are possible, despite they are confined in increasingly limited portions of the orbit of PX around its aphelion. They strongly depend on the location of the orbital plane of PX in space.
Fig. 14.— Simulated Earth-New Horizons range signature $\Delta \rho(t)$ due to a PX with (Batygin & Brown 2016a) $a_X = 700$ au, $e_X = 0.6$, $I_X = 30$ deg, $\omega_X = 150$ deg for $m_X = 10 \, m_\oplus$ (left column), $m_X = 15 \, m_\oplus$ (right column) obtained as a difference between two time series of $\rho(t) = \sqrt{(x_{NH}(t) - x_\oplus(t))^2 + (y_{NH}(t) - y_\oplus(t))^2 + (z_{NH}(t) - z_\oplus(t))^2}$ calculated by numerically integrating the barycentric equations of motion in Cartesian rectangular coordinates of all the major bodies of the Solar System and New Horizons over 3 years (2016–2019) with and without the perturber’s potential $U_X$ of Equation (1) (Hogg, Quinlan & Tremaine 1991). The initial conditions, corresponding to February 1, 2016, were retrieved from the WEB interface HORIZONS by NASA JPL; they were the same for both the integrations which share also the entire standard N–body dynamical models to the first post-Newtonian level. Upper row: $f_X$ is assumed as a free parameter varying in the range of Figure I while the perturber’s node is kept fixed at $\Omega_X = 113$ deg. Lower row: $\Omega_X$ is assumed as a free parameter varying in the range seemingly favored by Batygin & Brown (2016a), while the perturber’s true anomaly is kept fixed at $f_X = 150$ deg, within the allowed regions $D$ of Figure I. The arrival at 2014 MU$_{69}$, at about 43 au from the Sun, is scheduled for the beginning of 2019. During the cruise to it, the probe should coast mainly unperturbed, apart from the putative action of PX and a relatively small number of orbital maneuvers. The expected ranging precision is better than $\sigma_\rho = 10$ m up to 50 au (Fountain et al. 2008). It defines the light gray shaded area.
Fig. 15.— As in Figure 14, but with $\Omega_X = 100$ deg (upper row) and $f_X = 100$ deg (lower row).
Acknowledgements

I would like to thank an anonymous referee and H. Beust for their detailed and stimulating critical remarks which greatly improved the overall quality of the manuscript.
