ABSTRACT
It is widely believed that society is becoming increasingly polarized around important issues, a dynamic that does not align with common mathematical models of opinion formation in social networks. In particular, measures of polarization based on opinion variance are known to decrease over time in frameworks such as the popular DeGroot model. Complementing recent work that seeks to resolve this apparent inconsistency by modifying opinion models, we instead resolve the inconsistency by proposing changes to how polarization is quantified.

We present a natural class of group-based polarization measures that capture the extent to which opinions are clustered into distinct groups. Using theoretical arguments and empirical evidence, we show that these group-based measures display interesting, non-monotonic dynamics, even in the simple DeGroot model. In particular, for many natural social networks, group-based metrics can increase over time, and thereby correctly capture perceptions of increasing polarization.

Our results build on work by DeMarzo et al., who introduced a group-based polarization metric based on ideological alignment. We show that a central tool from that work, a limit analysis of variance-based polarization in future studies of opinion dynamics.

1.1 Our Approach and Main Results
Given the shortcomings of opinion variance as a measure of polarization, we address the central question of how to best quantify polarization by evaluating metrics through a dynamic lens. In particular, our goal is to identify natural metrics whose dynamics under simple models of opinion formation, like the DeGroot model, agree with observed dynamics of polarization in society.

Towards this end, we introduce a class of group-based metrics for polarization. We use “group-based” to reference the idea of a measure that is high when there are well-separated groups of individuals with different opinions. We formalize this notion in Section 2 by assuming shift- and scale-invariance, which are properties that

1 Actors like news agencies, social media companies, advertisers, and governments can influence opinions in a social network by swaying the strength of social connections possibly by promoting or hiding social media posts, creating fake user accounts and content, or running advertisements. By modeling these actions mathematically within an opinion dynamics framework, researchers can better understand how susceptible networks are to adversarial attacks [3, 27] and how “filter bubbles” emerge [11, 54].
naturally align with axiomatic treatments of clustering [41]. For now, we leave “group-based” as an intuitive definition and illustrate with an example. Consider the following opinion vectors on a six node social network (each entry is one individual’s opinion):

$$a = [-1, -6, -2, 2, 6, 1] \quad b = [5, 5, 5, -5, -5, -5]$$

While a has larger variance than b (2.8 vs. 1.5), b would have higher polarization under a group-based measure, since opinions are more clearly clustered into two distinct groups. This cluster structure could be quantified, for example, by any statistical measure of bimodality, like the popular Sarle’s bimodality coefficient [2]. Sarle’s coefficient is equal to $$(y^2 + 1)/\kappa$$, where y is skewness and $$\kappa$$ is kurtosis, and evaluates to 0.58 for a, but a higher value of 1 for b.

In this work, we explore two primary classes of related group-based measures:

**Statistical Measures (Section 4)** This class includes functions that, like Sarle’s bimodality coefficient, measure group structure in an opinion distribution by looking at moments beyond the second (i.e., beyond variance). For example, the bimodality coefficient incorporates third and fourth moment information.

**Local Measures (Section 5)** This class includes metrics that take into account local social connections on perceptions of group-structure. For example, we study local agreement, defined as the average percentage of an individuals social connections who agree on a particular topic (i.e., have an opinion on the same side of the mean). Networks with high local agreement may appear more polarized to individuals, who feel isolated in opinion bubbles.

We show that these group-based measures of polarization behave very differently than variance-based measures, exhibiting interesting, non-monotonic dynamics even in the simple DeGroot model. In particular, we prove that the group-based measures converge to values that depend on the structure of the underlying social network governing the opinion dynamics. As a result, instead of always converging to zero like variance-based measures, they can increase over time for certain networks. Our work builds on a result of DeMarzo, Vayanos, and Zwiebel [17], who study another group-based metric, which we call “ideological alignment”. Their work is based on an analysis of the limiting behavior of a normalized vector containing each individuals divergence from the mean opinion under the DeGroot opinion dynamics model. We show that this analysis extends to both statistical and local group-based polarization measures.

Moreover, we demonstrate empirically that increases in group-based polarization are not only possible, but actually common in natural synthetic and real-world social networks. A sample result for average local agreement measure (discussed in Section 5) appears in Figure 1. Dotted lines plot opinion standard deviation, a variance-based measure of polarization. Solid lines plot average local agreement, a natural group-based measure of polarization, discussed in Section 5. In contrast to standard deviation, for all networks the group-based measure increases over time, which is consistent with real-world perceptions of how polarization can evolve. This finding provides evidence that the group-based measure may be a more appropriate method for quantifying polarization than the variance-based one.

Figure 1: Number of iterations of DeGroot’s model vs. two measures of polarization in synthetic and real-world social networks. Dotted lines plot opinion standard deviation, a variance-based measure, while solid lines plot average local agreement, a natural group-based measure, discussed in Section 5. In contrast to standard deviation, for all networks the group-based measure increases over time, which is consistent with real-world perceptions of how polarization can evolve. This finding provides evidence that the group-based measure may be a more appropriate method for quantifying polarization than the variance-based one.

1.2 Conclusions and Recommendations
Our findings provide formal support for using group-based measures to quantify polarization in mathematical models of opinion dynamics. The unrealistic monotonic dynamics of variance-based measures have led past studies to abandon simple opinion models like the DeGroot dynamics, and to adopt alternative, more complicated models to mathematically recover interesting polarization dynamics. For example, the Friedkin-Johnson dynamics [24], bounded confidence model [45], and geometric models have all seen recent attention [26, 32]. A central conclusion of our work is that, alternatively, it may be the definition of polarization, not the model, that lacks richness for understanding societal polarization. By turning
from variance-based to natural group-based polarization measures, we see interesting dynamics even in the simplest models.

Beyond our work, the recommendation to use group-based measures is also supported by empirical evidence that these measures are more aligned with how individuals perceive polarization in society than variance-based metrics [21]. In particular, it has been argued that perceived polarization does not correlate with significant absolute differences in opinion (which drive overall opinion variance) [10, 44]. And while we cannot deny individual feelings of rising polarization in society, there is less evidence for increases in absolute difference in individual beliefs over time [5] [22]. It follows that the concept of “polarization” may not equate to the absolute differences in opinion measured by opinion variance. Instead, it has been argued that perceptions of polarization stem from perceptions of group-structure [44]. In fact, even the origin of the term “polarization” in the physical sciences suggests a group-based interpretation [1]. While sociological and psychological arguments for how to best quantify polarization are beyond the scope of this paper, the initial alignment between prior work and our findings is promising.

1.3 Relation to Prior Work

To the best of our knowledge, there has not been prior work on the problem of assessing the quality of various polarization metrics in mathematical models of opinion dynamics. Prior results have largely defaulted to variance-based measures. As mentioned, our work is most closely related to that of DeMarzo, Vayanos, and Zwiebel [17], whose limit analysis we adopt directly (providing a new proof in Section 3). The main novelty of our work over [17] is two fold. First, we show that the approach from [17] has implications for a wide class of group-based polarization measures. In particular, we show that the limit result from that work implies that other group-based polarization measures converge to graph dependent values, which can be large for some graphs. Second, for different group-based measures, we provide experimental evidence and novel theoretical arguments that these group-based measures will converge to large values for natural social networks.

2 PRELIMINARIES

Graph Notation. The DeGroot opinion dynamics model studied in this work is based on representing social connections via a weighted, undirected social graph, which we denote $G = (V, E)$. $G$ has $|V| = n$ nodes and $|E| = m$ edges, possibly including self-loops. Let $A$ be the adjacency matrix of $G$, with $A_{ij} = A_{ji} > 0$ if there is an edge between $i$ and $j$, and $A_{ij} = A_{ji} = 0$ otherwise. Let $N(i) \subseteq \{1, \ldots, n\}$ denote the set of neighbors of node $i$, which includes all $j$ for which $A_{ij} \neq 0$. If $G$ contains a self-loop at node $i$ then $A_{ii} > 0$ and $i \in N(i)$. Let $d_i = \sum_{j \in N(i)} A_{ij}$ denote the degree of node $i$ and let $D$ be a diagonal matrix containing $d_1, \ldots, d_n$ on its diagonal.

Vector Sign Normalization. For a non-zero vector $x$, let $|x|^b$ denote the vector $\text{sign}(x) \cdot |x|$, where $|x|$ is the first non-zero entry in $x$. That is, $|x|^b$ is equal to either $+x$ or $-x$, with the sign chosen to ensure that the first non-zero entry is positive.

2.1 DeGroot Opinion Dynamics

Mathematical models of opinion dynamics have been studied for decades in economics [34, 37, 46], applied math [38, 53], computer science [14, 59], and a variety of other fields [28, 52]. We refer the reader to the survey in [5]. Such models typically view society as a graph, where nodes represent individuals and edges represent social connections of various strength. Connections can be in-person relationships, online relationships (e.g., edges in an online social network), or both. Simple rules and procedures then define how an individual’s opinion on an issue (represented as a single discrete or continuous value, or as a vector) evolves over time.

We focus on one of the earliest and most elegant models of opinion formation: the DeGroot opinion dynamics [16, 23]. This model is based on the idea that opinions on a topic, encoded as continuous values, propagate through the social graph via simple averaging. Nodes incorporate the beliefs of their neighbors into their own opinion over time. We formally describe the model below.

**Definition 1 (DeGroot Opinion Dynamics).** Let $G = (V, E)$ be a weighted, undirected graph with $n$ nodes, $m$ edges, adjacency matrix $A$, and degree matrix $D$. For time steps $t = 0, 1, \ldots, T$, we associate the nodes of $G$ with an opinion vector $z(t) \in \mathbb{R}^n$ containing numerical values that represent each individual’s current view on an issue. Starting with a fixed vector of initial opinions $z(0)$, opinions under the DeGroot model evolve via the update:

$$z_i(t+1) = \frac{1}{D_{ii}} \sum_{j \in N(i)} A_{ij} z_j(t),$$

or equivalently, $z(t+1) = D^{-1} A z(t)$.

**Convergence to Consensus.** Like many other models of opinion dynamics, it is well known that the DeGroot dynamics converges to consensus in the limit. Formally, we have:

**Fact 1.** If $G$ is a connected, undirected, non-bipartite graph then,

$$z = \lim_{t \to \infty} z(t) \Rightarrow z \text{ if } c = \sum_{i=1}^{n} d_i z_i(0).$$

Note that $c$ is equal to the degree-weighted average opinion at time 0.

As discussed, a common approach to measuring polarization on a single issue at time $t$ is to consider the overall opinion variance:

$$\text{Var}[z(t)] = \|z(t) - \text{mean}(z(t)) \cdot 1\|_2^2$$

Of course, if all opinions converge to the same constant value $c$, as guaranteed by Fact 1, opinion variance eventually converges to zero. While this asymptotic observation only speaks to the model’s behavior after a very long time, in the short term, variance also tends to decrease monotonically with $t$, a fact that can be proven rigorously for regular graphs [12].

\footnote{The DeGroot model generalizes to directed graphs, but we consider the undirected case for simplicity.}
2.2 Group-based Polarization

In this work, we study group-based polarization metrics, which we broadly define to include any function with three properties:

- invariant to a shift in mean opinion, invariant to sign flips, and
- invariant to scaling. Formally:

**Definition 2 (Group-based Polarization).** Let \( f(G, z) \) be a function that maps an n-node graph \( G \) and vector of opinions \( z \in \mathbb{R}^n \) to a measure of polarization. Then \( f(G, z) \) is "group-based" if:

1. \( f(G, z) = f(-z) \),
2. \( f(G, z) = f(z + c\mathbf{1}) \) for any \( z \) and scalar \( c \), and
3. \( f(G, z) = f(cz) \) for any non-zero scalar \( c \).

While variance and statistical measures studied in Section 4 only depend on \( z \), the local measures studied in Section 5 do depend on the underlying social network which is why we include \( G \) as a parameter to \( f \). Variance-based measures of polarization satisfy properties (1) and (2) of Definition 2, but not (3). The last property reflects the fact that group structure should depend on relative differences in opinions instead of absolute differences. For example, an opinion vector would be considered polarized if we have two groups of individuals whose mean opinions are far apart regardless of the absolute differences.

The resulting requirement of scale-invariance has also appeared in axiomatic treatments of clustering objectives [41], which are closely related to group-based measures.

3 LIMIT ANALYSIS

While Fact 1 implies that any variance-based measure of polarization converges to zero, this is not true for the group-based measures. Since they are both shift and scale invariant, they are insensitive to both the mean opinion (this is also true of variance-based measures) and to uniform scaling of the opinions. As such, to analyze these measures, we prove a separate convergence result for the mean-centered, normalized opinion vector, which was also observed in [17]. In particular, we study the vector:

\[
\frac{z(t) - \text{mean}(z(t)) \cdot \mathbf{1}}{\|z(t) - \text{mean}(z(t)) \cdot \mathbf{1}\|_2}.
\]

We show that, under mild conditions, in the DeGroot model this vector converges to a fixed function of the second eigenvector of the normalized social network adjacency matrix, \( D^{-1/2}A \). We give a full proof below, which uses simpler arguments than [17].

**Theorem 1.** Let \( G \) be a connected graph with adjacency and degree matrices \( A \) and \( D \). Let \( v_1, \ldots, v_n \) and \( \lambda_1, \ldots, \lambda_n \) be the eigenvectors and eigenvalues of \( D^{-1/2}A \), in order of magnitude. I.e., \( |\lambda_1| \geq \ldots \geq |\lambda_n| \). Let \( z(0), \ldots, z(t) \) be a sequence of opinion vectors updated via the DeGroot opinion dynamics as in Definition 1. Let \( \bar{z}(t) = z(t) - \text{mean}(z(t)) \cdot \mathbf{1} \) be the mean-centered opinion vector at time \( t \), and let \( \bar{v}_2 = \frac{v_2 - \text{mean}(v_2) \cdot \mathbf{1}}{\|v_2 - \text{mean}(v_2) \cdot \mathbf{1}\|_2} \). If \( |\lambda_2| \neq |\lambda_3| \) and \((D^{1/2}v_2, z(0)) \neq 0\) then:

\[
\hat{x} = \lim_{t \to \infty} \frac{z(t)^	op}{\|z(t)\|_2} = \frac{\bar{v}_2 \hat{v}_t}{\|\bar{v}_2\|_2}.
\]

Recall that for a non-zero vector \( x \), \( |x|^\# \) denotes \(|x|^\# = \text{sign}(x_i) \cdot x \), where \( x_i \) is the first non-zero entry in \( x \).

**Proof.** From the linear algebraic form of the DeGroot update rule, we have that:

\[
z(t) = (D^{-1}A)^	op z(0) = D^{-1/2} \left( (D^{-1/2}A D^{-1/2} )^t \right) D^{1/2} z(0).
\]

Let \( D^{-1/2}AD^{-1/2} = \Sigma \Psi \Psi^T \) denote the eigendecomposition of the symmetric normalized adjacency matrix \( D^{-1/2}AD^{-1/2} \). \( \Sigma \) is a diagonal matrix that contains real-valued eigenvalues identical to those of \( D^{-1/2}A \). \( V \) is an orthogonal matrix whose columns contain eigenvectors \( v_1', \ldots, v_n' \) where \( v_i' = D^{1/2}v_i/\|D^{1/2}v_i\|_2 \). The eigenvalues of the normalized adjacency matrix of an undirected graph always lie in \([-1, 1]\) and, since \( A \) is connected, there is exactly one eigenvector with eigenvalue \( \lambda_1 = 1 \). It can be verified that the corresponding eigenvector of \( D^{-1/2}AD^{-1/2} \) is equal to \( v_1' = D^{1/2}v_1/\|D^{1/2}v_1\|_2 \).

We expand (1), using that \((D^{-1/2}AD^{-1/2})^t = \Sigma \Psi' \Psi^T \) since \( V \) is orthogonal. For \( i = 1, \ldots, n \), let \( c_i = \langle v_i, D^{1/2}z(0) \rangle \). We have that:

\[
z(t) = D^{-1/2} \cdot \left( c_1\lambda_1' v_1 + c_2\lambda_2' v_2 + \ldots + c_n\lambda_n' v_n \right),
\]

and thus \( \bar{z}(t) = z(t) - \text{mean}(z(t)) \cdot \mathbf{1} \) equals:

\[
\bar{z}(t) = c_1\lambda_1' D^{-1/2}v_1 - \text{mean}(c_1\lambda_1' D^{-1/2}v_1) \cdot \mathbf{1} + c_2\lambda_2' D^{-1/2}v_2 - \text{mean}(c_2\lambda_2' D^{-1/2}v_2) \cdot \mathbf{1}
\]

\[
\vdots
\]

\[
+ c_n\lambda_n' D^{-1/2}v_n - \text{mean}(c_n\lambda_n' D^{-1/2}v_n) \cdot \mathbf{1}.
\]

Note that \( D^{-1/2}v_i' \) is a scaling of the all ones vectors, so the first term in the sum above is zero. Letting \( \bar{v}_i = D^{-1/2}v_i' - \text{mean}(D^{-1/2}v_i') \), \( \bar{I} \), we are left with:

\[
\bar{z}(t) = \frac{c_2\lambda_2' \bar{v}_2 + c_3\lambda_3' \bar{v}_3 + \ldots + c_n\lambda_n' \bar{v}_n}{\|\bar{v}_2\|_2}.
\]

We first note that \( \|\bar{v}_i\|_2 > 0 \) for all \( i = 2, \ldots, n \). To see why this is the case, observe that to have \( \|\bar{v}_i\|_2 = 0 \), it must be that \( v_i' = cD^{1/2}v_1 \) for some constant \( c \). However, this cannot be the case because \( v_i' \) is orthogonal to \( v_1' = cD^{1/2}v_1 \). Combined with our assumption that \( c_2 = \langle D^{1/2}v_2, z(0) \rangle \neq 0 \), it follows that \( \|c_2\bar{v}_2\|_2 \geq 0 \). Then, by our assumption that \( |\lambda_2| \neq |\lambda_3| \), we have \( |\lambda_2| > |\lambda_4| \) for all

---

1Informally, suppose we are given a fixed adversarial example network with \( |\lambda_2| = |\lambda_3| \). A small random perturbation of the edges in the network will ensure that the second and third eigenvalue are no long exactly equal with high probability.

2There could be an eigenvalue with value –1, but we follow the convention that this would be denoted as \( \lambda_2 \).
Consider a social graph $G$ and $m$ different initial opinion vectors $\mathbf{z}_1^{(0)}, \ldots, \mathbf{z}_m^{(0)}$ satisfying the assumptions of Theorem 1. Apply the DeGroot opinion dynamics to each vector for $t$ steps to obtain opinions $\mathbf{z}_1^{(t)}, \ldots, \mathbf{z}_m^{(t)}$, and let $\mathbf{s}_t = \text{sign}(\mathbf{z}_1^{(t)} - \text{mean}(\mathbf{z}_1^{(t)})) \cdot 1$. Consider the matrix $\mathbf{S}_t = [s_1^{(t)}, \ldots, s_m^{(t)}]$. In the limit as $t \to \infty$, $\mathbf{S}_t$ will only contain two unique rows.

Each row of $\mathbf{S}_t$ corresponds to a single node (individual) in $G$. It contains $\{+1, -1\}$ entries indicating if that individual has opinion below or above the mean for each of the $m$ topics at time $t$. The row can thus be viewed an individual’s “binary opinion profile”. The takeaway from Corollary 2 is that, while there are $2^m$ possible opinion profiles, for large enough $t$ just two will dominate, becoming adopted by every individual. We visualized this alignment for four social networks in Figure 2. Opinions were initialized randomly, so the rows of $\mathbf{S}_t$ are distributed evenly between all $2^m$ possible binary opinion profiles. However, as $t$ increases, we eventually see convergence to a state where $\mathbf{S}_t$ has just two unique binary rows. The number of iterations until convergence varies by network.

While an interesting phenomenon, one potential limitation of ideological alignment as a polarization measure is that, like variance-based measures, it converges to the same extreme state for all social networks – albeit to a state that is fully polarized instead of a fully in consensus. In contrast, the other group-based measures of polarization discussed in this paper converge to network dependent quantities, so their dynamics over time will natural differ within different social structure and can be impacted by outside influences that effect that structure, like social media or propaganda.

### 3.2 Implications for Group-Based Polarization

The foundation of our work is the insight that Theorem 1 actually has implications on the limiting behavior of any group-based measure of polarization. Formally:

**Corollary 3.** Let $f(G, \mathbf{z})$ be a group-based polarization metric according to Definition 2 that is continuous with respect to the argument $\mathbf{z} \in \mathbb{R}^n$. If the conditions of Theorem 1 hold, then

$$\lim_{t \to \infty} f(G, \mathbf{z}^{(t)}) = f(G, \mathbf{v}_2)$$

where $\mathbf{z}^{(t)}$ and $\mathbf{v}_2$ are as defined as in Theorem 1.

Corollary 3 implies that, unlike variance-based measures which always converge to zero, under the mild assumptions of Theorem 1, any group-based measure of polarization converges to a value that depends on the social graph $G$. At the same time, the value does not depend on the starting opinions $\mathbf{z}^{(0)}$. With Corollary 3 in place, we analyze several different group-based measures of polarization in the subsequent sections.

### 4 STATISTICAL MEASURES

We start with statistical measures that, like variance, consider only the numerical values in an opinion vector $\mathbf{z}$, without taking into account the ordering of entries or their structure with respect to $G$. For example, the following common statistical measure of bimodality incorporates 3rd and 4th moment information from $\mathbf{z}$:
Bimodality

Change in Bimodality Over Time Given Random Initial Opinions

\(q\) will have bimodality with ity evolves in a highly non-monotonic way, it ultimately increases eigenvector of the SBM, which, at 2 orations, there is clear convergence to the bimodality of the second

\(p\) block is tic Block Model (SBM) network \([2, 35]\) on

graph, and initialized with five randomly generated

Groot’s opinion dynamics model run on the same 5 block

Figure 3: Opinion bimodality \(\beta(z)\) plotted by iteration of De-

Groot’s opinion dynamics model run on the same 5 block

SBM graph, and initialized with five randomly generated

start opinion vectors. As predicted by Corollary 3, in all
cases opinion bimodality converges to a fixed non-zero equi-

lrium bimodality that depends on the graph.

**Definition 3 (Sarle’s Bimodality Coefficient).** Consider an

opinion vector \(z\) and let \(\bar{z} = z - \text{mean}(z)\). Then the bimodality

\(\beta(z)\) is written in terms of the skewness \(\gamma\) and kurtosis \(\kappa\) as follows:

\[
\beta(z) = \frac{\gamma^2 + 1}{\kappa} \quad \text{where} \quad \gamma = \frac{\text{mean}(z^3)}{\text{mean}(z^2)^{3/2}} \quad \text{and} \quad \kappa = \frac{\text{mean}(z^4)}{\text{mean}(z^2)^2}.
\]

The bimodality coefficient of Definition 3 has been used as a

measure of opinion polarization, e.g. in [19], where it was compared against variance-based measures. The measure lies between 0 and 1, with 1 indicating maximum polarization. However, even a random

isotropic vector \(v\) (e.g., a vector with i.i.d. random Gaussian entries) will have bimodality \(\beta(v) \approx 1/3\), since the skewness of a normal random variable is 0 and the kurtosis is 3. Accordingly, we consider a vector of opinions “polarized” if the bimodality is larger than 1/3.

We demonstrate Corollary 3 in Figure 3. We generate a Stochas-
tic Block Model (SBM) network \([2, 35]\) on \(n = 1000\) nodes with five communities (blocks). The probability of an edge within a

block is \(p = 1/10\) and the probability of an edge between blocks is \(q = 1/100\). We then initialize five random starting opinion vectors, each with i.i.d. standard normal entries. We plot the bimodality of opinions as they evolve via the DeGroot dynamics. By 1000 itera-
tions, there is clear convergence to the bimodality of the second
eigenvector of the SBM, which, at \(t = 658\), is much larger than the bimodalities of the starting opinions around 1/3. So, while bimodality evolves in a highly non-monotonic way, it ultimately increases over time.

| 1st Quartile | Median | 3rd Quartile |
|--------------|--------|--------------|
| .805         | .917   | .952         |

Table 1: Statistics of equilibrium bimodality for 100 college social networks from the Facebook100 data set \([58]\).

Increases in bimodality are even more pronounced in real-world social networks. We ran a similar experiment for 100 college social networks from the Facebook100 data set \([58]\) and observed that for all but five networks, bimodality increases under the DeGroot dynamics with random starting opinions. The median and quartiles of the equilibrium bimodality (computed directly from the second eigenvector of each network) are included in Table 1. We conclude that the simple bimodality coefficient offers a clear contrast with variance-based measures of polarization that decrease over time.

An informal analysis of SBM graphs offers theoretical support for increases in bimodality in natural social networks with a small number of well connected communities. Specifically, we argue that any SBM with a small number of blocks typically has equilibrium bimodality greater than 1/3. We thus expect increasing bimodality under the DeGroot model if opinions are randomly initialized.

**Observation 1.** For a \(k\)-block SBM graph, the equilibrium bi-

modality is approximated by the sample bimodality of a normal random variable when \(k\) samples are taken, which has expected value greater than 1/3 for small \(k\).

We sketch a proof of Observation 1: While the bimodality of the normal distribution is 1/3, the empirical bimodality computed from a finite number of samples tends to over-estimate the true bimodality. While it is difficult to obtain an exact expression for the expectation of the sample bimodality, the sample kurtosis has

\[E[\kappa] \approx \frac{3}{k-1}\]

Sample kurtosis is thus an underestimate for small \(k\), explaining the overestimate of bimodality, which depends on the inverse kurtosis. Now consider the expected symmetric normalized adjacency matrix \(\bar{D}^{-1/2}\bar{A}\bar{D}^{-1/2}\) of an SBM graph, where \(\bar{D} = \mathbb{E}[\bar{D}]\) and \(\bar{A} = \mathbb{E}[\bar{A}]\). It is not hard to see that the top \(k\) eigenvectors of \(\bar{D}^{-1/2}\bar{A}\bar{D}^{-1/2}\) can be spanned by \(\bar{D}\) as well as \(k\) block indicator vectors, each of which is 1 for the nodes in a single community, and 0 for all other nodes. Since the actually normalized adjacency matrix \(\bar{D}^{-1/2}\bar{A}\bar{D}^{-1/2}\) can be viewed as a perturbed version of \(\bar{D}^{-1/2}\bar{A}\bar{D}^{-1/2}\), we roughly expect its first \(k\) eigenvectors to also be spanned by \(\bar{D}\) and the \(k\) block vectors – a formal statement could be made by appealing to the Davis-Kahan perturbation theo-

rem \([15]\). Moreover, the \(2^{nd}\) through the \((k-1)^{st}\) eigenvalues of \(\bar{D}^{-1/2}\bar{A}\bar{D}^{-1/2}\) are all the same, so we roughly expect the second
eigenvector of \(\bar{D}^{-1/2}\bar{A}\bar{D}^{-1/2}\) to be a random linear combination of the \(k\) block indicator vector, plus some scaling of \(\bar{D}\) (which has no impact on bimodality). If the random linear combination is isotropic, the second eigenvector will look exactly like \(k\) samples from a ran-
dom Gaussian distribution, each repeated \(n/k\) times. This vector the same bimodality as \(k\) random Gaussian samples.

Observation 1 is visualized in Figure 4, which was generated by computing the equilibrium opinion bimodality for 100 random \(k\)-SBM graphs with 1000 and 2000 nodes. While it approaches 1/3 as \(k\) increases, equilibrium bimodality is much larger for small \(k\). We also plot the sample bimodality of \(k\) i.i.d Gaussian samples (also computed using 100 trials), which as predicted by Observation 1, correlates well with the observed bimodality of the \(k\)-SBM.

\(^9\)Formally, we made an argument about the second eigenvector of \(\bar{D}^{-1/2}\bar{A}\bar{D}^{-1/2}\), whereas according to Corollary 3, it is the second eigenvector of \(\bar{D}^{-1}A\) that controls the equilibrium bimodality of a social network. However, since \(\bar{D}\) is close to a scaling of the identity for an SBM graph, these two vectors will be very similar to each other.
5 LOCAL MEASURES

Another interesting class of group-based polarization measures are those that take into account local structure of the social graph $G$. Such measures are motivated by the fact that individuals are most heavily exposed to the opinions of their social connections – i.e., their neighborhood in $G$. Individuals likely also have a sense of the overall mean opinion in $G$ (e.g., from the news), but do not simultaneously sense all opinions in a social network.

In this section we introduce and study one such measure, which we call average local agreement that takes these considerations into account. In particular, we define the local agreement of a vertex $i$ to be the ratio of $i$’s neighbors whose opinion falls on the same side of the mean opinion, $\text{sign}(x)$ as $i$. We posit that high local agreement correlates with high perceptions of polarization, as individuals who feel more isolated in a group, away from those differing opinions, tend to experience feelings of polarization [44].

We formally define average local agreement below. We use $\text{sign}(x)$ to denote the operation that rounds every entry of a vector $x$ to $+1$ or $-1$, taking the convention that if $x_i = 0$, $\text{sign}(x)_i = +1$.

**Definition 4 (Average Local Agreement).** Let $G$ be a social network on $n$ nodes and let $z \in \mathbb{R}^n$ be an opinion vector. Let $s = \text{sign}(z - \text{mean}(z) \cdot \mathbf{1})$. The average local agreement $L(G, z)$ equals:

$$L(G, z) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{d_i} \sum_{j \in N(i)} \mathbb{I}[s_j = s_i]$$

where $s = \text{sign}(z - \text{mean}(z) \cdot \mathbf{1})$.

Recall that $N(i)$ denotes the neighborhood of node $i$ in $G$, and $\mathbb{I}[-]$ is an indicator function that evaluates to 1 if the expression in brackets is true, and to 0 otherwise.

Like bimodality, average local agreement is a group-based measure as specified in Definition 2. So, as in Corollary 3, we have that in the DeGroot dynamics, under the assumptions of Theorem 1, $\lim_{t \to \infty} L(G, z(t)) = L(G, v_2)$, where $z(t)$ and $v_2$ are as defined as in the theorem. Average local agreement is bounded between $[0, 1]$ and we expect a value of 1/2 for randomly initialized opinions. So, any value above 1/2 is considered “polarized”. As shown in Table 2, we observe very high average local agreement in the limit for real-world social networks. For all but two of the 100 networks in the Facebook100 data set, this measure of polarization converged to a value above .6, and was typically well above .9. In Figure 5 we also visualize local agreement over time for a random 5-SBM graph and a random geometric graph, as well as the Swarthmore Facebook graph (chosen for its small size). In all cases, “bubbles” of high local agreement visibly emerge, with average local agreement increasing to .785, .954, and .941 for the three graphs, respectively.

**Table 2: Statistics of the equilibrium average local agreement, $L(G, v_2)$ for the Facebook100 data set [58].**

| 1st Quartile | Median | 3rd Quartile |
|--------------|--------|--------------|
| .904         | .947   | .960         |

To better understand the steep increase in this group-based polarization metric theoretically, we show that for an unweighted, regular graph $G$, average local agreement has a simple linear algebraic form. Ultimately, the following claim will help us relate the measure to spectral properties of the underlying social graph $G$.

**Claim 1.** Let $G$ be an unweighted $d$-regular graph with no self-loops. Let $z$ be a vector of opinions and let $s = \text{sign}(z - \text{mean}(z) \cdot \mathbf{1})$. Then, the average local agreement $L(G, z)$ equals:

$$L(G, z) = \frac{s^T A s}{2nd} + \frac{1}{2} \text{ where } s = \text{sign}(z - \text{mean}(z) \cdot \mathbf{1}).$$

**Proof.** For a node $i$, let $p_i = \sum_{j \in N(i)} \mathbb{I}[s_j = +1]$ denote the number of nodes in $N(i)$ that are on the positive side of the mean and let $q_i = \sum_{j \in N(i)} \mathbb{I}[s_j = -1]$ denote the number of nodes on...
the negative side of the mean. Let \( a_i \) denote the number of nodes in \( N(i) \) that agree with node \( i \) (i.e., are on the same side of the mean) and let \( b_i \) denote the number of nodes that disagree. We can write:

\[
a_i = \begin{cases} p_i & \text{if } s_i = +1 \\ q_i & \text{if } s_i = -1 \end{cases} \quad b_i = \begin{cases} p_i & \text{if } s_i = -1 \\ q_i & \text{if } s_i = +1 \end{cases}
\]

Observe that the \( i \)th entry of \( As \) equals \( p_i - q_i \), and thus:

\[
s^T As = \sum_{i=1}^{n} a_i - b_i = \sum_{i=1}^{n} a_i - \sum_{i=1}^{n} b_i.
\]

Next note that \( a_i + b_i = d \) and thus \( nd = \sum_{i=1}^{n} a_i + b_i \). So we have \( s^T As + nd = \sum_{i=1}^{n} 2a_i \). Dividing by \( 2nd \) gives the result because \( L(G, z) = \frac{1}{n} \sum_{i=1}^{n} a_i - b_i \).

With Claim 1 in place, we make the following observation:

**Observation 2.** For an unweighted graph \( G \), we can approximate the equilibrium average local agreement \( \lim_{t \to \infty} L(G, z(t)) \) by

\[
\lim_{t \to \infty} L(G, z(t)) \approx \frac{\lambda_2}{2} + \frac{1}{2},
\]

where \( \lambda_2 \) is the second eigenvalue of \( G \)’s normalized adjacency matrix.

According to this claim, we expect to see high equilibrium local agreement – i.e., increasing polarization – in any graph with a second eigenvalue close to \( 1 \), which includes any graph with strong community, and thus most natural social networks. For example, the Facebook100 networks had an average second eigenvalue of .871. Observation 2 predicts that this would lead to a mean equilibrium average local agreement of approximately .936, which is extremely close to the observed mean of .948.

To establish Observation 2, again assume that \( G \) is \( d \)-regular with no self-loops. Note that for a regular graph, the second eigenvalue of \( D^{-1/2} A \) is equal to that of \( D^{-1/2} A D^{-1/2} \). By Corollary 3, we have that \( \lim_{t \to \infty} L(G, z(t)) = L(G, v_2) \). And by Claim 1:

\[
L(G, v_2) = \frac{\text{sign}(v_2^T D^{-1/2} A) \text{sign}(v_2)}{2nd} + \frac{1}{2} = \frac{\text{sign}(v_2^T D^{-1/2} A D^{-1/2} \text{sign}(v_2))}{2n} + \frac{1}{2}
\]

Observation 2 then immediately follows by noticing that

\[
\text{sign}(v_2^T D^{-1/2} A D^{-1/2} \text{sign}(v_2)) \approx n v_2^T D^{-1/2} A D^{-1/2} v_2 = n \lambda_2.
\]

The approximation is exact if all entries in the unit vector \( v_2 \) have magnitude \( 1/\sqrt{n} \). It tends to hold a close approximation in other networks, which can be formalized via well-known connections between balanced cut problems and the second eigenvector [49, 57].

In Figure 6, we empirically confirm the relationship described in Observation 2 by examining a variety of random graphs with widely varying second eigenvalue. We find that the correlation between average local agreement and second eigenvalue in the Facebook100 data set is statistically significant (\( p = 5e^{-7} \)) with a Pearson correlation of \( r = .392 \).

Finally, we comment on the rate at which average local agreement converges to its equilibrium value. Since this rate depends on how quickly the normalized difference vector converges to \( s^* \) under the DeGroot model, we expect it to scale linearly with the inverse of the second eigenvalue gap, \( \frac{|\lambda_2 - |\lambda_1|}{|\lambda_2|} \). We confirm this relationship on the Facebook100 data set, where we see a statistically significant (\( p = 7e^{-6} \)) correlation between inverse second eigengap and average number of iterations until convergence to the final average local agreement when starting with a random opinion vector. The Pearson correlation coefficient of the relationship is \( r = .451 \).

In contrast, the rate at which the opinion vector converges to \( z^* \) depends inversely on the first eigengap \( \frac{|\lambda_1 - |\lambda_2|}{|\lambda_1|} \). As such, when the second eigengap is large compared to the first, we expect local agreement to increase more quickly than opinion variance decreases, which might contribute to perceptions of growing polarization.

**6 CONCLUSION**

In this work we established that natural group-based polarization measures display interesting dynamics under the standard DeGroot opinion formation model. Unlike heavily studied variance-based measures, we showed both empirically and theoretically that group-based measures can increase over time, and often do increase quite significantly in natural social networks.

We leave a number of questions for future research. As discussed, recent work on mathematical models of opinion dynamics has sought to understand the impact of outside actors (who can modify the graph \( G \) is some way) on individual opinions and polarization [3, 26]. There is little work on how such modifications impact group-based polarization, and if they can accelerate its emergence.

Another challenging question it to determine the “right” group-based measure of polarization for use in opinion dynamics studies. Our work establishes that group-based measures in general are more in line with real-world polarization than variance-based measures, but more in-depth studies of e.g. political opinion surveys would be needed to determine exactly which group-based measures best align with perceived polarization. Currently, there is some experimental evidence for the value of ideological alignment as a
meaningful polarization metric [22, 43], but statistical measures of bimodality and "local" metrics have received less attention.
