Sn$_x$P$_y$ Monolayers: a New Type of Two-Dimensional Materials with High Stability, Carrier Mobility, and Magnetic Properties

Yan-Mei Dou, Chang-Wen Zhang, Ping Li and Pei-Ji Wang *

Abstract

Searching for two-dimensional (2D) group V materials with ferromagnetism, elastic anisotropy, and carrier mobility and tunable band structure is one key to developing constantly developing nanodevices. The 2D monolayers Sn$_x$P$_y$ with $x/y$ (1/1, 1/2, 1/3, and so on) coordination number are studied based on the particle-swarm optimization technique combined with the density functional theory optimization. Its thermal stability can be confirmed by molecular dynamics at 70K and 300K, indicating that the novel 2D materials have a stable existence. The electronic band structures of four stable structures suggest that all the monolayers of Sn$_x$P$_y$ are fully adjustable and flexible tunable band gaps semiconductors under the biaxial strain. The monolayer of P$\overline{4}$2$_1$-m-SnP$_2$ with unique valence band structure can go from nonmagnetic to ferromagnetic by the hole doping because of the “Stoner criterion,” and Pmc$_2$1-SnP$_2$ is a direct-like gap semiconductor with in-plane elastic anisotropy to possess a high electron mobility as high as 800 cm$^2$V$^{-1}$s$^{-1}$ along the $k_b$ direction, which is much higher than that of MoS$_2$ ($\sim$ 200 cm$^2$V$^{-1}$s$^{-1}$). The optical absorption peak of the material is in the ultraviolet region. These discoveries expand the potential applications of the emerging field of 2D Sn$_x$P$_y$ structures in nanoelectronics.

Keywords: Sn$_x$P$_y$, Monolayers, Carrier mobility, Magnetic properties, Optical property

Introduction

Two-dimensional (2D) binary compounds have attracted extensive attention in recent years due to their unique properties and can provide reliable guidance for its potential applications in nanoelectronics and optoelectronic devices [1]. For instance, graphene attracted great interest since its discovery due to properties and potential applications [2–6], whereas graphene has undetectable small band gap at room temperature, making it difficult to use in optoelectronic nanodevices. So, these difficulties promoted researchers to resolve to find 2D materials with an ideal band gap. In the following years, boron-nitride (BN) [7], MoS$_2$ or other transition metal dichalcogenides [8–13], and transition-metal trichalcogenides [14, 15], among others are coming out. In recent years, graphene and other 2D materials of the group IV (silicone, stanene, and germanene [16]) have made good progress in scientific research. Except, 2D semiconductor materials belonging to the group V, especially phosphorene [17–19] and arsenene [20], are emerging as a new generation of contenders in the field of optoelectronic devices. Phosphene has broad application prospects in field-effect transistors, optoelectronic devices, spintronics, gas sensors and solar cells, and so on, while stanene, a 2D honeycomb-like structure, is considered to a new type of material with superior physical properties after graphene due to its strong electron spin-orbital coupling.

It is urgent to synthesize two kinds of elements to get multifunctional novel 2D materials. It is reported that alloying is often used to improve the properties of 2D materials to expand its applicability. For example, 2D MoS$_{2x}$Se$_{2(1-x)}$ and WS$_{2x}$Se$_{2(1-x)}$ nanosheets [21, 22] witness weird properties as tunable electronic, optical properties, and in-plane Negative Poisson’s Ratio with $x/$
density functional theory (DFT) [27, 28] methods were performed by using the plane-wave method to calculate electronic band structures suggest that all the stable or metastable monolayers with different coordination numbers are semiconductors with an indirect band gap. More importantly, the Pmc2_1-SnP_2 monolayer is a direct-like gap semiconductor with a finite band gap of 0.92 eV in the infrared-light region. But beyond that, the Pmc2_1-SnP_2 structure is a direct-like gap semiconductor that possesses high electron mobility of ~ 800 cm²V⁻¹s⁻¹, which is much higher than that of MoS₂ (~ 200 cm²V⁻¹s⁻¹). The monolayer of P T₂₁ m-SnP₂ structure with a unique valence band structure can go from nonmagnetic to ferromagnetic by the hole doping because of the “Stoner criterion.” The calculated electronic band structures suggest that all the monolayers of SnₓPᵧ are semiconductors with flexibly tunable band gaps under the biaxial strain, permitting strain engineering of four structures band gaps within nearly the whole visible-light range.

**Computational Methods**

In order to guarantee a thorough search of the structural diversity, various x and y selecting from one to six are taken into account on the basis of the particle swarm optimization (PSO) algorithm [26]. Results of the search delivered the monolayer structures are relatively steadily for y/x ≥ 1. To study the electronic structure of 2D SnₓPᵧ monolayers with different coordination number, our calculations were performed by using the plane-wave density functional theory (DFT) [27, 28] method to realize in the Vienna Ab-initio Simulation Package (VASP) [29–31]. Through the Generalized Gradient Approximation (GGA) to describe the exchange-correlation energy in the form of Per-dew–Burke–Ernzerhof (PBE) [32–35] and the electron-ion potential is described by the projection amplification wave method [33]. The cutoff energy of the plane-wave was chosen to be 500 eV energy for SnₓPᵧ systems, respectively. A sufficiently dense k point (9 × 9 × 1) of the reciprocal space was sampled in the Brillouin zone. The vacuum space perpendicular to the plane between neighboring super-cells is greater than 25 Å, eliminating the interaction between replicas. In the two consecutive steps calculation, it is set as 10⁻⁶ eV as the energy convergence value. During the geometric optimization, the atomic forces of all structures are less than 0.02 eV Å⁻¹ by using the conjugate gradient method until the atoms reach their optimal position. In addition, we will use the super-cell with 4 × 4 × 1 for ab initio molecular dynamic (AIMD) calculation when the Nosé algorithm [36] at 300K.

Carrier mobility is mainly affected by acoustic side wave scattering, optical side wave scattering, and ionized impurity scattering. Since the latter two are not as influential as the first one, the mobility we calculated includes the mobility under acoustic side wave scattering. Mobility mainly affects two performances of transistors: One is that the carrier concentration together determines the conductivity (the inverse of the resistivity) of the semiconductor material. Second, it affects the working frequency of the device. The main limitation of the frequency response characteristics of bipolar transistors is the time for minority carriers to cross the base region. Mobility is an important parameter to measure the conductivity of 2D semiconductor materials. It determines the conductivity of semiconductor materials and affects the working speed of devices. Thus, carrier mobility is controlled by phonon dispersion and can be described by the deformation potential (DP) theory which is proposed by Bardeen and Shockley [37]. So, the carrier mobility in 2D materials can be expressed as [38, 39]

\[ \mu_{2D} = \frac{2e\hbar^3C^{2D}}{3k_B T|m^*|^2E_1^2} \]

where e, h, and k_B are the electron charge reduced Planck and Boltzmann’s constant, respectively. And T is the temperature which set to 300K. Where m* is the effective mass, E₁ is deformation potential constant, and C_{2D} is the in-plane stiffness.

The linear effect of the system on the light field under the small wave vector is determined by the imaginary part of the complex dielectric constant and the dielectric function which can be calculated by

\[ \epsilon(\omega) = \epsilon_1(\omega) + i\epsilon_2(\omega) \]

where the \( \epsilon_1(\omega) \) and \( \epsilon_2(\omega) \) are the real part of the function and the imaginary part, \( \epsilon_1(\omega) \) can derive from the imaginary part \( \epsilon_2(\omega) \) the dielectric function by Kramer–Kronig
can be expressed [40]. The imaginary part of the dielectric function can be expressed as
\[ \varepsilon_2(\omega) = \frac{4\pi^2}{m^2 - \omega^2} \sum_{\nu, \lambda} \int d^3 \xi \frac{k^2}{2\pi^2} |e^\nu_{\xi\mu}|^2 \times \delta(E_C - \varepsilon_k - \varepsilon_{\xi\mu} - \hbar\omega) \]

In addition, the absorption coefficient \( I(\omega) \) was obtained by
\[ I(\omega) = \sqrt{2\omega} \left( \sqrt{\varepsilon_1^2(\omega) - \varepsilon_2^2(\omega) - \varepsilon_1(\omega)} \right) \frac{1}{2} \]

where the \( C \) is the conduction band, the \( V \) is valence band states, \( \Omega \) is the unit-cell volume, \( m \) is the mass of free electrons, \( e \) is the charge of free electrons, and \( \omega \) is the frequency of incident photons.

**Results and Discussion**

**Stability**

First, four 2D \( Sn_P_x \) monolayers were considered to determine their energetic stabilities. Formation energy is an energy parameter in a thermodynamic system which is a key point to check the stability of the system. The relative stability of \( Sn_P_x \) monolayers can be confirmed by computing the formation energy and is calculated as
\[ E_{form} = (E_{total} - N_{Sn}E_{Sn} - N_{P}E_{P})/(N_{Sn} + N_{P}) \]

where \( E \) is the energy of a compound or a constituent element at a specific pressure, \( N \) is the number of atoms in the unit cell. The negative formation energy of the calculated system indicates that the configuration is stable or metastable [41]. The calculated formation energies of \( Sn_P_x \) monolayers are -0.235, -0.223, -0.159, and -0.016 eV/atom (shown in Table 1), respectively. According to its definition, a smaller value indicates higher stability. Obviously, \( P\bar{6}m2-SnP \) is the most stable of these four structures. More particularly, the high thermal stability of semiconductor materials is particularly important in the application of electronic devices. Here, the thermal stability of the \( Sn_P_x \) monolayers examined by using ab initio molecular dynamics (AIMD) simulations. Based on the symmetries of the space groups, we just calculate the stability of \( P\bar{6}m2-SnP \) for similar structures \( P\bar{6}m2-SnP \) and \( Pmc21-SnP \) for \( Pmc21-SnP \) and \( P\bar{Z}21m-SnP \) structures. Results indicate that the average value of the total energy of the structure remains almost unchanged, and the structure remains unchanged after 1 ps, 3 ps, and 5 ps, suggest that \( Sn_P_x \) monolayers are thermally stable (in Figure S1). Then, we calculated phonon dispersion curves and have no imaginary vibrational frequencies implies that structures are dynamically stable (in Figure S1). Several methods have been reported in the literature to synthesize layered materials including micromechanical cleavage [2], epitaxial growth [42], chemical vapor deposition [43], and liquid exfoliation [44]. Some materials with the similar structure were successfully prepared experimentally. We have found some related reports that few layer GaSe nanosheets have been made into a high performance photodetector in the experiment [45]. In addition, the preparation, isolation, and rapid unambiguous characterization of large size ultrathin layers of MoS\(_2\), GaS, and GaSe deposited onto SiO\(_2\)/Si substrates are reported [46].

As plotted in Fig. 1a, b, the structures of \( P\bar{3}m1-SnP \) exhibit a structure similar to the \( P\bar{6}m2-SnP \) hexagonal phase. The \( Pmc21-SnP \) trigonal phase (Fig. 1c) exhibits that the \( x/y \) composition is further increased to 1/2. The material of a structure similar to \( P\bar{4}2_1m-SnP \) was proved stable by theory calculation [47]. Also, a new study finds the structure of \( XY_2 \) (Fig. 1d) is an indirect bandgap semiconductor, and it might susceptible to electric field and stress. We believe that the material we predict will have a successful preparation in the future with the development of technology.

**Electronic and Magnetic Properties**

The computed band structures and partial density of states of \( Sn_P_x \) monolayers are plotted in Fig. 2. As shown in Fig. 2a, the \( P\bar{6}m2-SnP \) is an indirect semiconductor with a band gap of 1.19 eV. The valence band maximum (VBM) at \( \Gamma \rightarrow K \) direction is contributed by the hybridized Sn-p and P-p orbitals, while the conduction band minimum (CBM) at \( K \) point derives from the hybridized Sn-s and P-p orbitals. \( P\bar{3}m1-SnP \) exhibits

---

**Table 1** Lattice parameters and calculated formation energy of the \( Sn_P_x \) monolayers

| \( Sn_P_x \) monolayers | Lattice parameters | Space group | Formation energy (eV/atom) |
|--------------------------|-------------------|-------------|--------------------------|
| \( P\bar{6}m2-SnP \)     | 3.95 3.95 17.16   | P\bar{6}m1  | -0.235                   |
| \( P\bar{3}m1-SnP \)     | 3.96 3.96 17.11   | P\bar{3}m1  | -0.223                   |
| \( Pmc21-SnP_2 \)        | 3.71 10.78 15.83  | Pmc21       | -0.159                   |
| \( P\bar{Z}21m-SnP_2 \)  | 7.59 7.59 14.66   | P\bar{Z}21m | -0.016                   |
similar electronic band structures as the $P6m2$-SnP counterpart but with a smaller band gap of 1.21 eV. The valence band dispersion of $P6m2$-SnP and $P3m1$-SnP near the Γ point and Fermi level ($E_F$) is quite flat, given the rather high density of states (DOS) and a van Hove singularity around the VBM. The $Pmc2_1$-SnP exhibits direct-like gap semiconducting character ($E_g(direct) - E_g(indirect) = 6$ meV) with a band gap of 0.72 eV (see Fig. 2c). Its VBM is mostly attributed to P-p orbitals, while its CBM is mainly contributed by P-p orbitals and Sn-s orbital. The $P421m$-SnP is an indirect-gap semiconductor with an $E_g$ of 1.79 eV, and the bands derive from is akin to Fig. 2c. More importantly, $P421m$-SnP monolayer has a similar condition compare with Fig. 2a, b, a flat-band dispersion character around the VBM also arises, resulting in very high DOS and a van Hove singularity.

According to Stoner criterion, spontaneous ferromagnetism occurs if the kinetic energy is smaller than the exchange splitting energy, which is if the DOS at $E_F$ is high enough. Figure 2d shown the very high DOS around the VBM; the $P421m$-SnP may satisfy the Stoner criterion.
criterion if its $E_F$ is shifted to a position with high DOS through hole doping. As shown in Fig. 3a, the hole doping can introduce magnetic moments at appropriate doping concentrations. As expected, the computation result suggests that the P421m-SnP2 may be converted into a ferromagnetic ground state beyond the critical hole density. Among them, the hole density $n_h$ can be expressed as $n_h = m_h/S_{cell}$ where $S_{cell}$ and $m_h$ are the area of the primitive cell and the number of holes introduced in the primitive cell. The injection of the hole into the monolayer P421m-SnP2 indeed leads to ferromagnetism. The magnetic moment exhibits a steep peak-like relationship with the hole density. Because an appreciable spin moment is induced by hole doping in the system, the energy band structure around the Fermi level has changed greatly due to spin splitting. Particularly, the spin-polarized band structure (shown in Fig. 3b) of P421m-SnP2 at $7.2 \times 10^{14}$ cm$^{-2}$ shows that the monolayer becomes a perfect half metal. So, we predict that the stable FM state with half metallicity can be realized in the P421m-SnP2 monolayer.

**Elastic Anisotropy and Carrier Mobility of Monolayer**

The strain effects on the electronic properties of the 2D monolayers Sn$_x$P$_y$ structures are also interesting. Figure 4a presents the energy gap variation under biaxial strain $\epsilon$. The energy gap of Sn$_x$P$_y$ monolayers is markedly modulated according to some rules. For example, the energy gap of P6m2-SnP decreases from 1.19 to 0.52 eV with the increasing tensile strain up to $\epsilon = 8\%$, first increasing from 1.12 to 1.36 eV for $\epsilon = 2\%$, then decreasing from 1.36 to 0.51 eV. In addition, since the $a$ and $b$ of the lattice parameter of the Pmc21-SnP$_2$ structure are different, the changes of electronic properties are different along the $x$-axis and $y$-axis [48], as shown in Fig. 4b. It is obvious that when uniaxial strain is applied in different directions, the change in the $x$ direction is different from the change in the $y$ direction. Considering the range of energy gaps with the strain $\epsilon$, the range of tunable band

**Fig. 3** Ferromagnetism in P421m-SnP2 monolayer. (a) Spin moments vs hole density $n_h$. (b) Computed valence band structure of P421m-SnP2 at $n_h = 7.2 \times 10^{14}$ cm$^{-2}$. The spin-up and spin-down bands are shown in blue and red, respectively. The Fermi level is set to be 0 eV.

**Fig. 4** Strain-dependent electronic properties of structures: (1) P6m2-SnP, (2) P3m1-SnP, (3) Pmc21-SnP$_2$, and (4) P421m-SnP$_2$. (a) Uniaxial strain dependent electronic properties of Pmc21-SnP$_2$. (b) Energy of the Pmc21-SnP$_2$ monolayer vs uniaxial strain.
gap by in-plane strain almost covers the entire visible-light region based on the first-principles calculation.

Besides, we also investigated the effect of uniaxial stress, as shown in Fig. 4c. The in-plane stiffness $C^{2D}$ ($C^{2D} = [\partial^2E/\partial\delta^2]/S_0$, where $S_0$ is the area of 2D Pmc21-SnP2 monolayer) can be obtained by fitting the parabola. Interestingly enough, the in-plane stiffness $C^{2D}$ showing extremely obvious elastic anisotropy along $a$ and $b$ directions are calculated to be 12.1 and 105.6 N/m, respectively. Because the Pmc21-SnP2 exhibits direct-like gap semiconducting character, the effective masses ($m^* = \hbar^2(\partial^2E/\partial K^2)^{-1}$) of electrons ($m^*_e$ is $|m^*_e|$) and holes ($m^*_h$ is $|m^*_h|$) associated with the (quasi) direct semiconducting Pmc21-SnP2 monolayer are also computed. The effective masses are listed (Table 2). Most interesting is the effective mass of electrons in the $k_b$ direction (0.15 me) is much smaller than that in the $k_a$ direction (1.31 me), indicating the easy drift of electrons in the $k_b$ direction.

There is another important parameter is DP constant $E_1 (E_1 = dE_{edge}/d\delta)$ for electrons along $a$ and $b$ directions is calculated to be 5.36 and 11.57 eV, respectively. Surprisingly, the calculated carrier can be achieved $\sim$ 800 cm$^2$V$^{-1}$s$^{-1}$ in the $k_b$ direction. As a comparison, the carrier mobility of the MoS2 monolayer is $\sim$ 200 cm$^2$V$^{-1}$s$^{-1}$ in experiments [8]. However, the carrier mobility is just about $\sim$ 8 cm$^2$V$^{-1}$s$^{-1}$ in the $k_a$ direction. Therefore, the high carrier mobility found in this study is of great significance for the study of electron transport.

**Optical Property**

The photoelectric properties of photoelectric materials are characterized by dielectric function, photoconductivity, and absorption coefficient. The imaginary parts of the dielectric function are shown in Fig. 5a. Note that Pmc21-SnP2 monolayer shows absorption starting at $\sim$ 0.70 eV, and there appear three main absorption peaks at $\sim$ 0.9, $\sim$ 3.2, and $\sim$ 4.0 eV. As illustrated in Fig. 5b, it shows the absorbance in all three directions in the visible range and ultraviolet range for monolayer Pmc21-SnP2. So, Pmc21-SnP2 monolayer materials could be used for atomically thin solar-blind photodetectors for, e.g., efficient detection of flames.

**Conclusions**

In conclusion, based on the PSO algorithms combined with first-principles calculations, we have identified several 2D Sn$_x$P$_y$ monolayers with the ratios of $x/y = 1:1$ and 1:2. Surprisingly, these novel monolayers also possess peculiar electronic and magnetic properties: the monolayer of $P\overline{4}2_1m$-SnP$_2$ structure with unique valence band structure can go from nonmagnetic to ferromagnetic by the hole doping because of the "Stoner criterion"; the Pmc21-SnP$_2$ structure is a direct-like gap semiconductor with in-plane elastic anisotropy is found to possess high electron mobility as high as 800 cm$^2$V$^{-1}$s$^{-1}$ along the $k_b$ direction, which is much higher than that of MoS$_2$ ($\sim$ 200 cm$^2$V$^{-1}$s$^{-1}$). The optical absorption peak of the material is in the ultraviolet region.

| Table 2 Effective masses of electrons and holes for Pmc21-SnP$_2$ |
|-----------------|-----------------|
| $|m^*_e|$ | 1.31 ($K_a$) | 0.15 ($K_b$) |
| $|m^*_h|$ | 0.42 ($K_a$) | 0.57 ($K_b$) |

Fig. 5a Computed dielectric functions versus energy for Pmc21-SnP$_2$ along different incident light directions. b Computed imaginary absorption coefficient.
discoveries expand the potential applications of the emerging field of 2D Sn$_{x}$P$_{y}$ structures in nanoelectronics. These desirable properties of the multifunctional Sn$_{x}$P$_{y}$ monolayers provide promising great applications in electronics and optoelectronics.
