ABSTRACT

Development of advance surface Electromyogram (sEMG)-based Human-Machine Interface (HMI) systems is of paramount importance to pave the way towards emergence of futuristic Cyber-Physical-Human (CPH) worlds. In this context, the main focus of recent literature was on development of different Deep Neural Network (DNN)-based architectures that perform Hand Gesture Recognition (HGR) at a macroscopic level (i.e., directly from sEMG signals). At the same time, advancements in acquisition of High-Density sEMG signals (HD-sEMG) have resulted in a surge of significant interest on sEMG decomposition techniques to extract microscopic neural drive information. However, due to complexities of sEMG decomposition and added computational overhead, HGR at microscopic level is less explored than its aforementioned macroscopic-level, DNN-based counterparts. In this regard, we propose the HYDRA-HGR framework, which is a hybrid model for HGR that simultaneously extracts a set of temporal and spatial features through its two independent Vision Transformer (ViT)-based parallel architectures (the so-called Macro and Micro paths). The Macro Path is trained directly on the pre-processed HD-sEMG signals, while the Micro path is fed with the p-to-p values of the extracted Motor Unit Action Potentials (MUAPs) of each source. Extracted features at macroscopic and microscopic levels are then coupled via a Fully Connected (FC) fusion layer for final gesture classification. We evaluate the proposed HYDRA-HGR framework through a recently released HD-sEMG dataset, and show that it significantly outperforms its stand-alone counterparts. The proposed HYDRA-HGR framework achieves average accuracy of 94.86% for the 250 ms window size, which is 5.52% and 8.22% higher than that of the Macro and Micro paths, respectively.

Index Terms— Biological Signal Processing, Deep Neural Networks, Hand Gesture Recognition, sEMG Decomposition.

1. INTRODUCTION

In recent years, development of prosthetic Human-Machine Interface (HMI) systems [1] has greatly improved lives of those suffering from amputated limb(s) or neuromuscular disorders. Generally speaking, recent HMI systems [2] are mainly controlled with a learning model developed based on Biological Signal Processing (BSP) algorithms. Learning-based algorithms developed for potential use in prosthetic HMI devices are primarily comprised of advanced Machine Learning (ML) models [3] or Deep Neural Networks (DNNs) [4] that perform Hand Gesture Recognition (HGR) via surface Electromyogram (sEMG) signals. To secure high performance and proper control in HGR tasks, attention is directed to DNNs and/or hybrid architectures because of their proven capabilities in tackling challenging real-life problems [5–7]. Such models, however, are still prone to several major challenges such as high latency, large training times, undue complexity, and difficulty in finding the discriminative patterns in sEMG signals of different hand gestures. Accordingly, designing an accurate HGR method that can be effectively adopted in an HMI system addressing the above-mentioned issues is the centerpiece of today’s gesture recognition-based research works.

Literature Review: sEMG signals measure the electrical activities of the underlying motor units in limb muscles and are collected non-invasively from the electrodes placed on skin surface [8]. In particular, High Density sEMG (HD-sEMG) signals are acquired through a two-dimensional (2D) grid with a large number of closely-located electrodes [9], capturing both temporal and spatial information of muscle activities. HD-sEMG acquisition, therefore, provides superior spatial resolution of the neuromuscular system in comparison to its sparse acquisition counterpart. This has inspired targeted focus on development of DNN-based HGR methods based on HD-sEMG signals [10–13]. Broadly speaking, HD-sEMG-based BSP approaches can be classified into the following two main categories:

(i) Raw HD-sEMG Processing for HGR: Algorithms belonging to this category directly use raw HD-sEMG signals for the task of HGR. In this context, e.g., Reference [11] performed instantaneous training of a Convolutional Neural Network (CNN) using a 2D image of a single time measurement. In [12], Recurrent Neural Networks (RNNs) are combined with CNNs to create a hybrid attention-based [14] CNN-RNN architecture, which has improved HGR performance due to joint incorporation of spatial and temporal features of HD-sEMG signals. Sun et al. [13] introduced a network of dilated Long Short-Term Memories (LSTMs) to classify hand gestures from the transient phase of HD-sEMG signals.

(ii) HD-sEMG Decomposition: The focus here is on HD-sEMG decomposition to extract microscopic neural drive information. HD-sEMG signals have encouraged emergence of sEMG decomposition algorithms in the last decade [15] as they provide a significantly high-resolution 2D image of Motor Unit (MU) activities in each time point. sEMG decomposition refers to a set of Blind Source Separation (BSS) [16] methods that extract discharge timings of motor neuron action potentials from raw HD-sEMG data. Single motor neuron action potentials are summed to form Motor Unit Action Potentials (MUAPs) that convert neural drive information to hand movements [17]. Motor unit discharge timings, also known as Motor Unit Spike Trains (MUSTs), represent sparse estimations of the MU activation times with the same sampling frequency and time interval as the raw HD-sEMG signals [18].
Extracted MUSTs are used in several domains such as identification of motor neuron diseases [19], analysis of neuromuscular conditions [20], and myoelectric pattern recognition [21].

A third category can be identified when the extracted MUSTs in Category (ii) are used for HGR at microscopic level. HD-sEMG signals are modelled as a spatio-temporal convolution of MUSTs, which provide an exact physiological description of how each hand movement is encoded at neuromuscular level [22]. Thus, MUSTs are of trustworthy and discernible information on the generation details of different hand gestures, which leads to adoption of another group of HGR algorithms that accept MUSTs [23] as their input. Nevertheless, due to complexities of the decomposition stage and added computational overhead, microscopic level HGR using MUST is less explored than models of Category (i), which use HD-sEMG signals at a macroscopic level. There are, however, some promising works [1, 21, 24] in which MUSTs carrying microscopic neural drive information are exploited for HGR instead of directly using raw sEMG signals. To discover a direct connection between different hand gestures and extracted MUSTs, these methods have suggested estimating MUAPs of the identified sources and extracting a set of useful features from MUAPs that are unique for each hand gesture. For instance, in [21], the peak-to-peak (p-to-p) values of MUAPs are calculated for each MU and each electrode channel separately and a 2D image of MUAP p-to-p is constructed for all the channels of a single MU. Afterwards, this 2D image is fed to a CNN architecture and its performance is compared to that of traditional ML methods. In short, using HD-sEMG decomposition results for HGR is still in its infancy, and in this paper, we aim to further advance this domain.

Contributions: In this paper, for the first time to the best of our knowledge, we introduce the idea of integrating the macroscopic and microscopic neural drive information obtained from HD-sEMG data into a hybrid framework for HGR. As indicated in [5, 10], Vision Transformers (ViTs) [25] are proved to surpass the most popular DNN architectures like CNNs and hybrid CNN-RNN models in HGR tasks, using either sparse or HD-sEMG datasets. Being motivated by this fact, here, we propose a framework that consists of two independent ViT-based architectures that work on the basis of the attention mechanism [10]. While one of these ViTs is trained directly on the preprocessed HD-sEMG data, the other one is fed with the p-to-p values of the extracted MUAPs of each source. Thereby, a set of temporal and spatial features of various hand movements are extracted from HD-sEMG signals and MUAPs, which are then fused via a Fully Connected (FC) fusion layer for final classification. We show that by extracting a very small number of underlying sources (maximum of 7 sources in this case), the proposed method improves the overall classification accuracy compared to its counterparts. In brief, contributions of the paper are as follows:

- Introducing, for the first time to the best of our knowledge, the idea of integrating macroscopic and microscopic neural drive information through a hybrid DNN framework for HGR.
- Simultaneous utilization of raw HD-sEMG signals and extracted MUSTs from HD-sEMG decomposition via parallel construction of two ViT-based architectures.

2. MATERIALS AND METHOD

In this section, we introduce the dataset used to develop the proposed hybrid HYDRA-HGR model and we briefly describe the transformer architecture as its building block.

2.1. Dataset

The utilized dataset [26] in this study is a HD-sEMG collection of 20 non-disabled participants that performed 65 isometric hand movements in 5 repetitions. One of the movements is performed twice, therefore, we have 66 gestures in total. The dataset is a set of 1-, 2-
3. PROPOSED HYDRA-HGR ARCHITECTURE

The main objective of the proposed model is to classify a given trial of HD-sEMG signals to either of the underlying 66 hand gestures. In this section, we present the proposed hybrid ViT-based architecture that couples HD-sEMG signals and their extracted MUAPs for HGR. The HYDRA-HGR framework simultaneously extracts a set of temporal and spatial features through its two independent ViT-based parallel paths. The Macro Path is trained directly on the pre-processed HD-sEMG signals, while the Micro path is fed with the p-to-p values of the extracted MUAPs of each source. A fusion path, structured in series to the parallel ones and consisting of FC layers, then combines extracted temporal and spatial features for final gesture classification.

3.1. Macro Path: Extraction of Macroscopic Information

In this sub-section, we present the Macro Path of the HYDRA-HGR framework, which directly learns from raw HD-sEMG signals. As HD-sEMG signals are of 3 dimensions, i.e., one dimension in time and two dimensions in space, they can directly be fed to a ViT that is designed for 3D images. The raw HD-sEMG signals, however, should be first pre-processed to be entirely compatible with the ViT’s input format. First, the positive envelope of the data is found via a low-pass butterworth filter (at 1Hz), which is applied to signals of each electrode independently [10, 11]. Then, the filtered signals are normalized through the \( \mu \)-law algorithm [28], which increases the selectivity power of the model. Following that, each HD-sEMG repetition is split into windows of size 512 (250 ms) with a skip step of 256, which means 50\% of overlap among consecutive windows. The proposed framework takes each data segment with shape (512,8,16) as input and outputs the predicted label among 66 gestures.

3.2. Micro Path: Extraction of Microscopic Neural Drive Info.

Here, first, we present the fundamentals of the developed BSS algorithm for extracting MUSTs from HD-sEMG signals. Then we elaborate on how the HYDRA-HGR framework is employed for classification of MUAPs as a by-product of the BSS method. Multi-channel sEMG signals are generated as a convolutive mixture of a set of impulse trains representing the discharge timings of multiple MUs, i.e.,

\[
x_i(t) = \sum_{l=0}^{L-1} \sum_{j=1}^{N} h_{ij}(l)s_j(t-l) + \nu_i(t),
\]

where \( x_i(t) \) is the \( i^{th} \) channel’s EMG data (from the entire \( M \) channels); \( h_{ij}(l) \) is the action potential of the \( j^{th} \) MU (from the entire \( N \) extracted MUs) measured at the \( i^{th} \) channel; \( s_j(t) \) is the MUST at the \( j^{th} \) MU, and; \( \nu_i \) is the additive white noise at channel \( i \). Additionally, \( t \) is the time index; \( D \) is the duration of sEMG recordings; and \( L \) is the duration of MUAPs. Eq. (4) is represented in matrix form as

\[
X(t) = \sum_{l=0}^{L-1} H(l)S(t-l) + \nu(t),
\]

where \( X(t) = [x_1(t), \ldots, x_M(t)]^T \) and \( S(t) = [s_1(t), \ldots, s_N(t)]^T \) are the recordings of all the \( M \) electrode channels and the MUSTs of all the \( N \) extracted sources at time \( t \), respectively. Term \( H(l) \) is the \((M \times N)\) matrix of action potentials, which is considered to be constant in duration \( D \). The convolutive equality of Eq. (5) is the basic BSS assumption.

The objective is to find the maximum number of independent matrices \( S(t) \) from Eq. (5) if \( X(t) \) is the only known parameter. Eq. (5) can be written in an instantaneous form, where the source vectors are extended with their \( L-1 \) delayed contributions. Additionally, to adapt the model for BSS conversions, the observation vectors are extended with their \( T \) delayed versions, resulting in the following final convolutive model: \( \hat{X}(t) = \hat{H} S(t) + \hat{\nu}(t) \), where each of the \( \hat{X}(t) \), \( \hat{H} \), \( \hat{S}(t) \), and \( \hat{\nu}(t) \) are the extended versions of the observation, MUAPs, sources, and noise matrices, respectively. Among the existing BSS approaches [15] suggested for HD-sEMG decomposition, gradient Convolution Kernel Compensation (gCKC) [29,30] and fast Independent Component Analysis (fastICA) [31] are of great prominence and frequently used in the literature. To achieve better accuracy, the utilized BSS algorithm [15] is a combination of gCKC [29,30] and fastICA [31] algorithms. In the gCKC method, the MUSTs are estimated using a linear Minimum Mean Square Error (MMSE) estimator as follows

\[
\hat{s}_j(t) = \hat{C}^{-1}_{w,s} C_{w,s} x(t),
\]

in which \( \hat{s}_j(t) \) is the estimate of the \( j^{th} \) MUST at time \( t \), \( \hat{C}_{w,s} \approx E[(x(t)\hat{s}_j^T(t))] \) is approximation of the unknown cross-correlation vector between the MUSTs and the observations, and \( C_{w,s} = E[(x(t)x^T(t))] \) is the correlation matrix of observations. Term \( E[\cdot] \) indicates the mathematical expectation. According to Eq. (6), as \( \hat{C}_{w,s} \) is unknown, a blind estimation of MUSTs is iteratively found with gradient descent [29]. On the other hand, in the fastICA, the goal is to estimate separation vectors \( w \) such that

\[
\hat{s}_j(t) = w^T_k(Z(t)),
\]

where \( \hat{s}_j \) is the \( j^{th} \) MUST; \( w_j \) is the \( j^{th} \) separation vector; and \( Z \) is the whitened matrix of observations. The separation vectors are identified through the fixed-point optimization algorithm [15, 31]. Note that term \( k \) in Eq. (7) denotes the separation vector identifying fixed-point iterations. To provide analogous inputs for the Macro and Micro ViT-based models, we extracted MUSTs for windowed HD-sEMG signals of shape (512,8,16), separately. The number of iterations for estimating a new source is set to 7, therefore, a maximum of 7 sources that are either sparse or uncorrelated at time lag zero are found for each window. The length of MUAPs (\( L \)) that are computed from extracted MUSTs in the next step are assumed to be 20 samples. Furthermore, it is empirically shown that extension factors greater than 16 have almost the same impact on the number and quality of extracted MUSTs [15]. Here, we set the extension factor to 20 and the silhouette threshold determining which sources are of acceptable quality in each iteration to 0.92.

After extracting MUSTs for all the windows, the MUAP waveform for each channel and each extracted MU is calculated with the Spike-Triggered Averaging (STA) technique [1]. Following the work of [32], MUSTs are divided by a sliding window of 250 samples with skip size of 256; a MUAP of length 20 is calculated for each window distinctly and the results are summed to give the final MUAP waveform. In such a way, 128 (\( 8 \times 16 \)) MUAPs are acquired for each extracted source. In the final stage, the p-to-p values of each MUAP is
for each window, and \( 512 \) temporally are concatenated and flattened. Here, gesture FC layers at the end of each network that take the class token for the two ViT-based paths), each model is trained separately for HGR. Before fusing the Macro and Micro neural information (extracted via 3.3. Combining the Two ViT-based Architectures

of the p-to-p values, respectively. The patch size is set to \((8 \times 8)\) implying that there are 64 temporal patches for each window. The model’s embedding dimension \((d)\) is 128 and the patches are divided into 8 parallel heads in the transformer encoder. Adam optimizer is used with learning rate of 0.0001 and weight decay of 0.001. The network is trained with 20 epochs with each batch containing 128 data samples. In the second experiment, 2D MUAP p-to-p images are fed to the Micro ViT-based architecture. In this architecture, the image size and the number of input channels are set to \((8 \times 16)\). The patch size is set to \((8 \times 8)\) implying that there are 2 spatial patches for each p-to-p image, each corresponding to an \((8 \times 8)\) electrode grid. The model’s embedding dimension \((d)\) and number of heads is the same as its Macro counterpart. Similarly, Adam optimizer is used with learning rate of 0.0003 and weight decay of 0.001. The network is trained with 50 epochs with each batch containing 64 data samples. Each data sample, in this case, has a maximum of 7 MUAP p-to-p images. Finally, in the third experiment, both Macro and Micro ViT-based architectures are frozen, the feature vectors/matrices from each model are concatenated and fed to two trainable FC layers. This network is trained with 20 epochs and a batch size of 128 samples. Similarly, Adam optimizer is used with learning rate of 0.0005 and weight decay of 0.0001. A comparison of each model’s accuracy and STD for each fold is represented in Table 1. The box plots showing accuracy, InterQuartile Range (IQR) and the results for Wilcoxon’s signed-rank test between each pair of the 3 models is represented in Fig. 3. As can be seen in Table 1, the Macro Model’s accuracy is, \(\approx 3-4\%\) better than that of the Micro Model for each fold. However, the HYDRA-HGR improves the accuracy of each fold by at least 3% and the average accuracy of all the folds by 5.52% compared to the Macro model. According to Fig. 3, the discrepancy between the average accuracy of the proposed HYDRA-HGR and each of the stand-alone models is also statistically significant with \(p\)-values \(\leq 1 \times 10^{-4}\).

5. CONCLUSION
In this paper, a DNN-based model for classification of hand gestures from HD-sEMG signals is proposed in which two ViT-based architectures are fused to outperform the case of adopting each architecture singly. The training procedure in the proposed method comprises two stages: During the former, ViT-based architectures are trained separately on HD-sEMG signals and p-to-p values of the extracted MUAPs from raw HD-sEMG signals. In the latter, both models’ weights are kept fixed and the feature sets obtained in the last layer are joined and given to two FC layers for final classification. We show that the classification accuracy of the fused framework is, on average, 5.52% and 8.22% greater than that of Macro and Micro Models, respectively.

### Table 1. Comparison of classification accuracy and STD for each fold and their average. The accuracy and STD for each fold is averaged over 19 subjects.

| Model’s Name           | Fold1(%)  | Fold2  | Fold3   | Fold4   | Fold5   | Average       |
|-----------------------|-----------|--------|---------|---------|---------|---------------|
| Stand-alone Macro Model | 79.92 \(\pm\) 3.39 | 91.43 \(\pm\) 2.48 | 93.84 \(\pm\) 2.05 | 92.57 \(\pm\) 2.28 | 88.96 \(\pm\) 2.83 | 89.34 \(\pm\) 2.61 |
| Stand-alone Micro Model | 81.53 \(\pm\) 3.45 | 88.03 \(\pm\) 2.66 | 89.63 \(\pm\) 2.39 | 89.11 \(\pm\) 4.02 | 84.92 \(\pm\) 2.97 | 86.64 \(\pm\) 3.10 |
| The HYDRA-HGR          | 89.38 \(\pm\) 2.88 | 96.86 \(\pm\) 1.82 | 96.82 \(\pm\) 1.75 | 96.65 \(\pm\) 2.75 | 94.61 \(\pm\) 1.90 | 94.86 \(\pm\) 2.22 |

Fig. 2. (a) Diagram of the adopted procedures for obtaining MUAP p-to-p images. (b) MUAPs for a single MU of the first windowed signal corresponding to the first repetition of gesture 1. The MUAPs are estimated/shown for each channel separately. (c) p-to-p values of MUAPs represented as a 2D image. (d) 3D representation of MUAP p-to-p values.

Fig. 3. Boxplots, IQR and Wilcoxon’s signed-rank test for the 3 models over all the 19 subjects.

The HYDRA-HGR is the number of extracted MUs is \(1024\) \(\times\) \(19\), which is fed into two trainable FC layers to perform the final classification.
