Fluorescence microscopy and scanning nearfield optical microscopy and spectroscopy were used to characterize cyanine dyes adsorbed to mica surfaces. The formation of J-aggregates was confirmed, and furthermore it was found that the J-aggregates show a fluorescence-intensity dependent spectral shift. Brighter, and thus larger aggregates show a red-shift in fluorescence spectra of up to 3 nm. [DOI: 10.1380/ejssnt.2005.94]

Keywords: J-aggregate; SNOM; size-effect

I. INTRODUCTION

Thin films of organic materials are often required for many applications in photonic science. Dye aggregates or dye crystals often show different characteristics (absorption and fluorescence spectra, excited state lifetime, excited state relaxation, etc.) than the molecularly dispersed or amorphous state. Thus it is of utmost importance to control the aggregation state and to measure the photonic response.

It is known since the 1930ies that cyanine dyes can be used as photosensitizers in photographic films [1]. Cyanine dyes form so-called J-aggregates in solution and in spin-coated polymer films. J-aggregates show a characteristic red-shift of absorption and fluorescence spectra. Furthermore, the spectral width is only 10–20 nm, which is much narrower than the molecular dispersed state.

The spectral shape and the absorption and fluorescence maxima can be controlled by confining J-aggregates into micron sized polymer droplets, so-called ‘microdomes’ [2, 3].

Here we report on the adsorption of cyanine dyes onto mica surfaces and in polyer microdomes and the spectral shift of the resulting J-aggregates depending on the aggregate fluorescence intensity. Scanning nearfield optical microscopy (SNOM) was used, since it allows for a sub-micrometer resolution. Previous experiments [2, 3] used far field microscopy with a lateral resolution of 2 µm. Since the polymer domes have a spacing larger than that, individual microdomes can be investigated. In the case of adsorption of the dye onto mica, the aggregate density is higher and thus a better lateral resolution is necessary. Furthermore, the topography of the sample can be recorded simultaneously, and not in to separate measurements, as in the case of far field microspectrometry.

II. EXPERIMENTAL

The cyanine dye (N, N’-diethyl-9-methylthiacarbocyanine iodide, NK77, see Fig. 1) (Aldrich) was dissolved in chloroform (p.a., Merck, Germany) and approx. 100 µl of a 0.2 mM solution was placed close to the edge of a glass slide or a freshly cleaved mica substrate of 2 cm × 5 cm. A glass roller was used to cast the solution uniformly over the whole...
substrate. The roller speed was 5 mm/min and 10 mm/min, respectively. Fluorescence microscopic images were obtained with an Olympus BX-51 microscope equipped with a color CCD camera (SPOT-RT, Diagnostics Inc.). Scanning nearfield optical micrographs were taken under illumination/collection mode (NFS-230K, JASCO, Japan, see Fig. 2) in which the sample was excited through a fiber (aperture 410 nm) with laser light of 532 nm. The fluorescence was collected by the same fiber and the fluorescence spectrum was recorded for each spot of a 21×21 point matrix, covering 20 µm × 20 µm of the sample. The spectral resolution was < 0.19 nm.

III. RESULTS

Figure 3 shows the fluorescence micrographs of NK77 adsorbed onto glass and freshly cleaved muscovite mica. The excitation wavelength was 440−480 nm and the fluorescence emission > 520 nm was detected, by using a far field fluorescence microscope. The glass sample shows a non-uniform coverage of the surface with large aggregates having a large variation in brightness. In contrast, the mica surface is homogeneously covered with aggregates with diameters of 1−3 µm. It is known that cationic cyanine can adsorb onto the negatively charged mica surface to form J-aggregates [4]. Direct investigation of the dye aggregates by atomic force microscopy showed epitaxial growth of the aggregates with an aggregate height of a few nanometers [5].

First evidence for the effect of the J-aggregate size on the photophysical properties have been obtained from conventional far-field microspectroscopy of microscopic mica flakes, on which J-aggregates were adsorbed [6]. It was found that larger flakes of a diameter of around 10 µm give rise to a red-shifted fluorescence, as compared to flakes with a diameter of 1−3 µm. Furthermore, the J-aggregates on larger mica flakes were more stable against photobleaching. Both findings led to the conclusion that larger flakes produce larger J-aggregates, and that the larger J-aggregates are more stable and show red-shifted fluorescence [6].

Figure 4 shows the mapping of a 20 µm × 20 µm area of a large mica substrate, which is covered with J-aggregates...
TABLE I: Spectral characteristics of the three spectra in Fig. 4. Position refers to the position of the spectrum in Fig. 4.

| Position (x, y) | Peak (nm) | Peak Intensity (arb. unit.) | Half-width (nm) |
|----------------|-----------|----------------------------|-----------------|
| (3,-6)         | 611.1     | 13                         | 11.3            |
| (3,6)          | 610.7     | 10                         | 10.0            |
| (-7,3)         | 609.7     | 3                          | 12.1            |

The characteristics (maximum fluorescence wavelength, peak intensity and spectral width) of the three spectra are summarized in Table 1. There is a correlation between fluorescence intensity (inferred from the peak height) and the maximum fluorescence wavelength. Although small, there is a distinct shift of the fluorescence to longer wavelengths for brighter, and thus larger aggregates. The half width of the spectra seems not to be correlated with the peak intensity.

Figure 5 shows the correlation between peak intensity and peak wavelength for several spectra for two samples: 5 mm/min roller speed and 10 mm/min.

It is evident that the spectra shift to longer wavelength for both samples, even though the effect is more pronounced for the sample prepared at higher roller speed. It has already been reported that the fluorescence spectra of cyanine dye J-aggregates embedded in polymer 'microdomes' show a similar effect. Larger domes lead to red-shifted aggregates. This can be explained by the formation of larger J-aggregates in larger domes, since there are more molecules in the larger domes that can diffuse and aggregate. Thus it was possible to tailor the emission wavelength of a fluorescent material by changing the size of the physical confinement into micrometer-sized domes. In the present results, the size of the aggregates cannot be exactly determined yet. Still, the size was inferred from the fluorescence intensity and a similar effect of the dependence of fluorescence wavelength and emission maximum was found.

This new finding confirms that the fluorescence shift with aggregate size is not a measurement artefact due to re-absorption of fluorescence light by the J-aggregates in the three dimensional polymer microdomes. The J-aggregates on mica are known to have a thickness of just a few molecules, which rules out re-absorption in this quasi two-dimensional geometry. Furthermore, the illumination/collection mode of the SNOM also ensures no re-absorption of the fluorescence light.
