Heterogeneous Distributed Average Tracking

Salar Rahili, Wei Ren

Abstract—This paper addresses distributed average tracking for a group of heterogeneous physical agents consisting of single-integrator, double-integrator and Euler-Lagrange dynamics. Here, the goal is that each agent uses local information and local interaction to calculate the average of individual time-varying reference inputs, one per agent. Two nonsmooth algorithms are proposed to achieve the distributed average tracking goal. In our first proposed algorithm, each agent tracks the average of the reference inputs, where each agent is required to have access to only its own position and the relative positions between itself and its neighbors. To relax the restrictive assumption on admissible reference inputs, we propose the second algorithm. A filter is introduced for each agent to generate an estimation of the average of the reference inputs. Then, each agent tracks its own generated signal to achieve the average tracking goal in a distributed manner. Finally, numerical example is included for illustration.

I. INTRODUCTION

In many applications of multi-agent systems, agents are required to compute the summation of individual time-varying inputs in a distributed manner. For example, in sensor fusion [1], feature-based map merging [2], distributed Kalman filtering [3], and distributed optimization [4], computing the average of individual reference inputs is an inseparable part of the algorithms and hence this problem attracted a significant attention recently.

In this paper, an average tracking problem for a team of heterogeneous agents is studied, where each agent uses local information to calculate the average of individual time-varying reference inputs, one per agent. Here, the average of individual reference inputs is time-varying and it is not available to any agent; hence distributed average tracking introduces additional complexities and theoretical challenges compared to the consensus and leader-followers problems.

Researchers have introduced linear distributed algorithms as one of the earlier approaches addressing this problem [5]–[8]. In [6], a proportional-integral algorithm is proposed to achieve distributed average tracking for slowly-varying reference inputs with a bounded tracking error. In [7], through the use of the internal model principle, an algorithm is introduced for a special group of time-varying reference inputs with a common denominator in their Laplace transforms. In [8], a distributed average tracking problem is solved, with steady-state errors, while the privacy of each agent’s input is preserved.

However, in linear algorithms, the reference inputs are required to satisfy restrictive constraints and most of the results only can guarantee to have a bounded error. Therefore, some results based on nonlinear tracking algorithms have been published recently [9], [10]. A class of nonlinear algorithms is introduced in [9], where it is proved that for reference inputs with bounded deviations the tracking error is bounded. In [10], a nonsmooth algorithm is proposed for reference inputs with bounded derivatives.

However, all the aforementioned studies addressed the distributed average tracking problem from an estimation perspective, where the agents do not have a certain physical dynamics. There are various applications, where the distributed average tracking problem is employed as a control law for physical agents [11]. For example, multiple agents moving in a formation with local information and interaction might need to cooperatively figure out what optimal trajectory the virtual leader or center of the team should follow, where each individual agent specifies its motion using that knowledge. Distributed average tracking can be employed in this problem, where each agent can construct its own reference input using the gradient of its own local cost function [4]. A distributed average tracking algorithm is proposed in [12], for physical agents with double-integrator dynamics, where the reference inputs are allowed to have a bounded accelerations. A distributed algorithm without using velocity measurements for a group of physical second-order agents is introduced in [13], where the reference input are assumed to have bounded accelerations’ deviations. However, this algorithm is not robust to position and velocity initialization errors. Therefore, it is modified in [14] to remove the initialization constraint and communication between agents.

However, in real applications physical agents might have more complicated dynamics rather than single-integrator or double-integrator dynamics. There are only a few studies, that have addressed more complicated dynamics. For example, in [15], the problem is studied for physical agents with general linear dynamics, where reference inputs are bounded. A class of algorithms is proposed in [16], to achieve distributed average tracking for physical Euler-Lagrange systems, where it is proved that a bounded error is achieved for reference inputs with bounded derivatives. In [17], a distributed average tracking algorithm is proposed for physical second-order agents, where there is a nonlinear term in both agents’ and reference inputs’ dynamics.

In most of the studies in the literature, agents are assumed to be identical. There are only few works assumed nonidentical parameters or nonidentical additive terms in agents’ dynamics [16], [17]. However, in real applications, we might need to employ different agents (robots) with different abilities to accomplish a task. In these scenarios, agents obey completely different physical dynamics. To the best of our knowledge, the heterogeneous average tracking problem in the literature has been limited to the case that the reference inputs are time-

invariant, where the problem is transformed into a distributed consensus \cite{18-20}. In heterogeneous distributed consensus algorithms, there always exists a term forcing the velocity of each individual agent to zero. This tremendously reduces the complexity of the problem. However, in dynamic average tracking problem, our goal is to track a time-varying trajectory, where a precise control on velocities and accelerations of the agents is required. It is worthwhile to mention that having a heterogeneous multi-agent system consisting of agents with different dynamics, it is not possible to employ the algorithms proposed for homogeneous dynamics, corresponding to each agent’s dynamic, and expect to have a well-behaved system. Therefore, a careful analysis considering the interaction among the agents with different frameworks is needed.

In this paper, a heterogeneous framework consisting of agents with three different dynamics, single-integrator, double-integrator and Euler-Lagrange dynamics, is considered. Two nonsmooth algorithms are proposed to achieve the distributed average tracking goal. In our first proposed algorithm, each agent is required to have access to only its own position and the relative positions between itself and its neighbors. In some applications, the relative positions can be obtained by using only agents’ local sensing capabilities, which might in turn eliminate the communication necessity between agents. To relax some restrictive assumptions on admissible reference inputs, we propose an estimator-based algorithm, where a filter is introduced for each agent to generate an estimation of the average of the reference inputs. Then, each agent tracks its own filter’s variables with its neighbors.

The transpose of matrix \( A \) and vector \( x \) are shown as \( A^T \) and \( x^T \), respectively. Let \( 1_n \) and \( 0_n \) denote the \( n \times 1 \) column vector of all ones and all zeros respectively. Let \( \text{diag}(a_1, \ldots, a_p) \) be the diagonal matrix with diagonal entries \( a_1 \) to \( a_p \). We use \( \otimes \) to denote the Kronecker product, and \( \text{sgn}(\cdot) \) to denote the signum function defined componentwise. For a vector function \( x(t) : \mathbb{R} \rightarrow \mathbb{R}^m \), define \( \| x \|_p \) as the p-norm. The cardinality of a set \( S \) is denoted by \( |S| \).

An undirected graph \( G \triangleq (V, E) \) is used to characterize the interaction topology among the agents, where \( V \triangleq \{1, \ldots, n\} \) is the node set and \( E \subseteq V \times V \) is the edge set. An edge \((j, i) \in E\) means that node \( i \) can obtain information from node \( j \) and vice versa. Self edges \((i, i)\) are not considered here. The adjacency matrix \( A \triangleq [a_{ij}] \in \mathbb{R}^{n \times n} \) of the graph \( G \) is defined such that the edge weight \( a_{ij} = 1 \) if \((j, i) \in E\) and \( a_{ij} = 0 \) otherwise. For an undirected graph, \( a_{ij} = a_{ji} \). The Laplacian matrix \( L \triangleq [l_{ij}] \in \mathbb{R}^{n \times n} \) associated with \( A \) is defined as \( l_{ii} = \sum_{j \neq i} a_{ij} \) and \( l_{ij} = -a_{ij} \), where \( i \neq j \). For an undirected graph, \( L \) is symmetric positive semi-definite. By arbitrarily assigning an orientation for the edges in \( G \), let \( D \triangleq [d_{ij}] \in \mathbb{R}^{n \times |E|} \) be the incidence matrix associated with \( G \), where \( d_{ij} = -1 \) if the edge \( e_j \) leaves node \( i \), \( d_{ij} = 1 \) if it enters node \( i \), and \( d_{ij} = 0 \) otherwise. The Laplacian matrix \( L \) is then given by \( L = DD^T \) \cite{21}.

**Lemma 2.1**: \cite{21} For a connected graph \( G \), the Laplacian matrix \( L \) has a simple zero eigenvalue such that \( 0 = \lambda_1(L) < \lambda_2(L) \leq \ldots \leq \lambda_n(L), \) where \( \lambda_i(\cdot) \) denotes the \( i \)th eigenvalue. Furthermore, for any vector \( y \in \mathbb{R}^n \) satisfying \( 1^T y = 0 \), we have \( \lambda_2(L)y^2 \leq y^T Ly \leq \lambda_n(L)y^2 \).

**Corollary 2.1**: \cite{22} Consider the system,

\[
\dot{x} = f(x, t),
\]

where \( x(t) \in D \subseteq \mathbb{R}^n \) and \( f : D \times [0, \infty) \rightarrow \mathbb{R}^n \) and \( D \) is an open and connected set containing \( x = 0 \), and suppose is Lebesgue measurable and is essentially locally bounded, uniformly in \( t \). Let \( V : D \times [0, \infty) \rightarrow \mathbb{R} \) be locally Lipschitz and regular such that

\[
W_1(x) \leq V(x, t) \leq W_2(x)
\]

\[
\dot{V} \leq -W_2(x),
\]

\[\forall t \geq 0, \forall x \in D, \text{ where } W_1 \text{ and } W_2 \text{ are continuous positive definite functions, and } W \text{ is a continuous positive semi-definite function on } x \in D \text{ and } \dot{V} \text{ is the generalized gradient of function } V. \text{ Choose } r > 0 \text{ and } c > 0 \text{ such that } B_r \subseteq D \text{ and } c < \min W_1(x). \text{ Then, all Filippov solutions of } (1) \text{ such that } x(t_0) \in \{x \in B_r \mid W_2(x) \leq c\} \text{ are bounded and satisfy } W(x) \rightarrow 0 \text{ as } t \rightarrow \infty.\]

### III. Problem Statement

Consider a heterogeneous multi-agent system consisting of \( N \) physical agents, where \( \mathcal{I} \) denotes the index set \{1, \ldots, N\}. The agents’ are described by single-integrator, double-integrator and Euler-Lagrange dynamics. Without loss of generality, we label single-integrator agents as \( 1, \ldots, M - 1 \), where their dynamics is described by

\[
\dot{x}_i = u_i, \quad i = 1, \ldots, M - 1.
\]

We also label double-integrator agents as \( M, \ldots, N' - 1 \), with dynamics described by

\[
\dot{x}_i = u_i, \quad \ddot{u}_i = u_i, \quad i = M, \ldots, N' - 1.
\]

Agents with Euler-Lagrange dynamics are labeled as \( N', \ldots, N \), and their dynamic is described by

\[
M_i(x_i)\ddot{x}_i + C_i(x_i, \dot{x}_i)\dot{x}_i + g_i(x_i) = u_i, \quad i = N', \ldots, N,
\]

where \( x_i(t) \in \mathbb{R}^p, \dot{v}_i(t) \in \mathbb{R}^p \) and \( u_i(t) \in \mathbb{R}^p \) are, respectively, \( i \)th agent’s position, velocity and control input.
M_i(x_i) is the p × p symmetric inertia matrix, C_i(x_i, ̇x_i) ̇x_i is the Coriolis and centrifugal force, and g_i(x_i) is the vector of gravitational force. The dynamics of the Lagrange systems satisfy the following properties \cite{23}:

(P1) There exist positive constants k_M, k_T, k_p such that 
\[ k_M l_p \leq M_i(x_i) \leq k_M l_p, \| C_i(x_i, ̇x_i) ̇x_i \| \leq k_T \| ̇x_i \| \text{ and } \| g_i(x_i) \| \leq k_g \].

(P2) \[ M_i(x_i) = 2C_i(x_i, ̇x_i) \] is skew symmetric.

(P3) The Lagrange dynamics can be rewritten as, i.e.,
\[ ̇M_i(x_i, ̇x_i, ̇ν_i) + C_i(x_i, ̇x_i) ̇ν_i + g_i(x_i) = Y_i(x_i, ̇x_i, ̇ν_i)θ_i, \forall x_i, ν_i \in \mathbb{R}^p, \text{where } Y_i \in \mathbb{R}^{p \times p} \text{ is the regression matrix and } θ_i \in \mathbb{R}^p \text{ is the unknown but constant parameter vector.}

In our framework the agents’ interaction topology is described by an undirected graph G.

**Assumption 3.1:** Graph G is connected.

Suppose that each agent has a time-varying reference input \( r_i(t) \in \mathbb{R}^p, i \in I, \) satisfying
\[ ̇r_i(t) = v_i^r(t), \]
\[ ̇v_i^r(t) = a_i^r(t), \] \( \text{for agents with single-integrator dynamics and} \)
\[ u_i = -\beta_i \text{sgn} \left[ \sum_{j=1}^{N} a_{ij}(x_i - x_j) \right] - \sum_{j=1}^{N} a_{ij}(x_i - x_j) \]
\[ - (x_i - r_i) - 2(v_i - v_i^r) + a_i^r, \] \( i = M, \ldots, N' - 1 \)
\[ \text{for agents with double-integrator dynamics and} \]
\[ u_i = Y_i(x_i, ̇x_i, v_i, ν_i) ̇θ_i - α s_i \]
\[ - \sum_{j=1}^{N} a_{ij}(x_i - x_j), \] \( i = N', \ldots, N \)
\[ ν_i = -β_i \text{sgn} \left[ \sum_{j=1}^{N} a_{ij}(x_i - x_j) \right] - (x_i - r_i) + v_i^r, \]
\[ s_i = ̇x_i - ν_i, \]
\[ ̇θ_i = -Y_i(x_i, ̇x_i, ν_i, ν_i)^T s_i, \] \( \text{for agents with Euler-Lagrange dynamics, where } α \text{ and } β_i \text{ are positive constant gains to be designed, and } θ_i \text{ is the estimate of the unknown but constant parameters } θ_i. \text{Using the definition of the generalized gradient } \cite{24}, \text{the generalized time-derivative of } s_i \text{ and } v_i \text{ are defined, respectively, as } ̇θ_i \text{ and } ν_i, \text{ where } ζ_i \in ̇θ_i, \text{ and } μ_i \in ν_i. \text{Let } ̇ξ_i \text{ denotes the minimum norm element of } ν_i. \text{Proof:} \]

**Theorem 3.3:** Under the control law given by \cite{3}–\cite{10} for system defined in \cite{3}–\cite{5}, distributed average tracking goal \cite{7} is achieved asymptotically, provided that Assumptions 3.1 and 3.2 hold and the control gain \( β_i \) is chosen such that \( \min_{ι \in Χ} β_i > ̇r + ̇v^r \) and \( α > 0 \).

\[ \lim_{t \to \infty} |r_i(t)| - \frac{1}{N} \sum_{j=1}^{N} r_j(t) | = 0, \] \( \text{where each agent has only local interaction with its neighbors.} \)

**A. Distributed Average Tracking for Heterogeneous Physical Agents Using Neighbors’ Positions**

In this subsection, we study the distributed average tracking problem for heterogeneous multi-agent system consisting of three different dynamics, single-integrator, double-integrator and Euler-Lagrange dynamics. Here, we propose an algorithm to achieve goal \cite{7}, where each agent is required to have access to only its own position and the relative positions between itself and its neighbors. Note that in some applications, these pieces of information can be obtained by sensing; hence the communication necessity might be eliminated. For notational simplicity, we will remove the index \( t \) from variables in the reminder of the paper.

Three controllers are proposed, where each agent according to its dynamic will employ the proper control \( u_i \). Consider the control input
\[ u_i = -β_i \text{sgn} \left[ \sum_{j=1}^{N} a_{ij}(x_i - x_j) \right] - (x_i - r_i) + v_i^r, \] \( i = 1, \ldots, M - 1, \)
for agents with single-integrator dynamics
\[ \dot{x}_s = - \beta_s \text{sgn}((L_s \otimes I_p)x) - (x_s - r_s) + v_s^r, \] \( \text{where } r_s = [r_1^T, \ldots, r_{M-1}^T]^T, \) and \( v_s^r = [v_1^r, \ldots, v_{M-1}^r]^T \), denote, respectively, the aggregated reference inputs and reference velocities of the single-integrator dynamic \cite{3} and \( β_s = \text{diag}(β_1, \ldots, β_{M-1}) \). System \cite{4} with control input \cite{9} can be rewritten in vector form as
\[ \dot{x}_d = v_d \]
\[ \dot{v}_d = - β d \text{sgn}((L_d \otimes I_p)x) - (L_d \otimes I_p)x - (x_d - r_d) - 2(v_d - v_d^r) + a_d^r, \] \( \text{for agents with double-integrator dynamics and} \)
\[ u_i = Y_i(x_i, ̇x_i, v_i, ν_i) ̇θ_i - α s_i \]
\[ - \sum_{j=1}^{N} a_{ij}(x_i - x_j), \] \( i = N', \ldots, N \)
\[ ν_i = -β_i \text{sgn} \left[ \sum_{j=1}^{N} a_{ij}(x_i - x_j) \right] - (x_i - r_i) + v_i^r, \]
\[ s_i = ̇x_i - ν_i, \]
\[ ̇θ_i = -Y_i(x_i, ̇x_i, ν_i, ν_i)^T s_i, \] \( \text{for agents with Euler-Lagrange dynamics, where } α \text{ and } β_i \text{ are positive constant gains to be designed, and } θ_i \text{ is the estimate of the unknown but constant parameters } θ_i. \text{Using the definition of the generalized gradient } \cite{24}, \text{the generalized time-derivative of } s_i \text{ and } v_i \text{ are defined, respectively, as } ̇θ_i \text{ and } ν_i, \text{ where } ζ_i \in ̇θ_i, \text{ and } μ_i \in ν_i. \text{Let } ̇ξ_i \text{ denotes the minimum norm element of } ν_i. \text{Proof:} \]

**Theorem 3.3:** Under the control law given by \cite{3}–\cite{10} for system defined in \cite{3}–\cite{5}, distributed average tracking goal \cite{7} is achieved asymptotically, provided that Assumptions 3.1 and 3.2 hold and the control gain \( β_i \) is chosen such that \( \min_{ι \in Χ} β_i > ̇r + ̇v^r \) and \( α > 0 \).

\[ \lim_{t \to \infty} |r_i(t)| - \frac{1}{N} \sum_{j=1}^{N} r_j(t) | = 0, \] \( \text{where each agent has only local interaction with its neighbors.} \)
where \( v_d = [v_M^T, ..., v_{N-1}^T]^T \), \( r_d = [r_M^T, ..., r_{N-1}^T]^T \), \( \beta_d = [\beta_M, ..., \beta_{N-1}]^T \), and \( \alpha_d = [\alpha_M, ..., \alpha_{N-1}]^T \) denote, respectively, the aggregated velocities, reference inputs, reference velocities and reference accelerations of the double-integrator system (4) and \( \beta_d = \text{diag}(\beta_M, ..., \beta_{N-1}) \).

It follows from (P3) that \( M(x_e)\dot{x} = C(x,e,x_e)\dot{x}_e + Y(x,e,x_e,u,v)\nu \) where \( M(x_e) \triangleq \text{diag}(M_N(x_N), ..., M_N(x_N)) \), \( C(x,e,x_e) \triangleq \text{diag}(C_N(x_N,x_e), ..., C_N(x_N,x_e)) \), and \( u_e = [u_N^T, ..., u_N^T]^T \). Now, by replacing the control input \( \tilde{u} \), we have

\[
M(x_e)\dot{x} + C(x,e,x_e)\dot{x}_e + Y(x,e,x_e,u,v)\nu \theta - \alpha s - (L_e \otimes I_p)x,
\]

where \( \zeta, \nu, \theta \) and \( \tilde{\theta} \) are, respectively, the column stack vectors of all \( \zeta_i, \nu_i, \theta_i \) and \( \tilde{\theta}_i \), \( i = N, ..., N \). Let \( \beta_e = \text{diag}(\beta_N, ..., \beta_N) \). Let \( r = [r^T, r^T, r^T]^T \), and \( v^r = [v^r, v^r, v^r]^T \) denote, respectively, the aggregated reference inputs, and reference velocities for all agents.

Define the Lyapunov function \( V_i \) as

\[
V_i = \frac{1}{2} x^T (L_i \otimes I_p)x + \frac{1}{2} (v_d - \Phi)^T (v_d - \Phi) + \frac{1}{2} \beta_s (\hat{M} - \tilde{\theta}) + \frac{1}{2} \hat{M} s^T \hat{M} - \alpha \theta - \alpha_0 \theta - \chi - \chi - \alpha_0 \alpha_0\]

where \( \Phi(x) = -\beta_d \text{sgn}[(L_d \otimes I_p)x] - (x_d - r_d) + v^r_d \), and \( \hat{\theta} = \hat{\theta} - \theta \). It is easy to see that we have \( V_i \leq V_i \) since \( e = \Phi^T x = 0 \) and \( D = \text{def} \). Hence \( V_i \) is a positive definite function corresponding to \( e \). The candidate Lyapunov function \( V_i \) satisfies the following inequalities:

\[
W_1(y) \leq V(y,t) \leq W_2(y),
\]

where \( y = \begin{bmatrix} x & v_d - \Phi \end{bmatrix} \) and \( W_1 \) and \( W_2 \) are positive-definite continuous functions defined as \( W_1 = \Lambda_1 \| y \|^2 \) and \( W_2 = \Lambda_2 \| y \|^2 \), where \( \Lambda_1 \) and \( \Lambda_2 \) are positive constants.

Define the generalized gradient of \( V_i \) and \( \Phi \) by \( \dot{V}_i \) and \( \dot{\Phi} \), respectively. Every element of \( \eta \) satisfies

\[
\eta - x^T (L_i \otimes I_p) \hat{\dot{\beta}} = \frac{\text{sgn}[(L_i \otimes I_p)x]}{\text{sgn}[(L_i \otimes I_p)x]} + x^T (L_i \otimes I_p) \left( \begin{array}{c} 0 \\ v_d - \Phi \\ s \end{array} \right) \left( \begin{array}{c} -x_d + r_d + v^r_d \\ -x_d + r_d + v^r_d \\ -x_e + r_e + v^r_d \end{array} \right) + (v_d - \Phi)^T \left( -\beta_d \text{sgn}[(L_d \otimes I_p)x] - (L_d \otimes I_p)x \right) - (x_d - r_d) - 2(v_d - v^r_d) + a_d^T - \frac{1}{2} \hat{M} s^T \hat{M} - \alpha \theta - \alpha_0 \theta + s^T \left( -C(x_e, x_e) s - Y(x_e, x_e, v, v) \hat{\theta} - \alpha \theta \right) - s^T (L_e \otimes I_p)x,
\]

where \( \hat{\beta} = \text{diag}(\beta_s, \beta_d, \beta_p) \), and \( \rho \in \hat{\Phi} \) and we used the fact that we can rewrite equations (12) and (10), respectively, as

\[
x_d = \dot{\Phi} + v_d - \dot{\Phi} + \hat{\beta}
\]

and

\[
\dot{\theta} = -\beta e \text{sgn}[(L_e \otimes I_p)x] - (x_e - r_e) + v^r_e + s.
\]

Employing (10), we have

\[
\eta \leq -\min_{i \in \mathbb{I}} \left[ \| (L_i \otimes I_p)x \|_1 - x^T (L_i \otimes I_p)x \right] + x^T (L_i \otimes I_p)(r + v^r) + x^T (L_d \otimes I_p)(v_d - \Phi) + x^T (L_e \otimes I_p)^T (v_d - \Phi) - (v_d - v^r) + a_d^T - \frac{1}{2} s^T \hat{M} s - \alpha s^T s
\]

where \( x \leq -x^T (L_i \otimes I_p)x + (v_d - \Phi)^T (v_d - \Phi) - \alpha_0 \alpha_0 \) is zero wherever \( v(x, v, t) \) is differentiable. Also at points of non-differentiability, we will have \( \chi - \varphi = 0 \). Hence,

\[
\eta \leq -x^T (L_i \otimes I_p)x + (v_d - \Phi)^T (v_d - \Phi) - \alpha_0 \alpha_0 s.
\]

We can see that \( \dot{V}_i \leq -W(y) \), where \( W \) is a positive semi-definite defined on the domain \( D = \mathbb{R}^{N(3p + np)} \). As a result \( V_i \in \mathcal{L}_\infty \), and \( \theta, s, \nu, (v_d - \Phi) \in \mathcal{L}_\infty \).

By calling \( z = x_e - r_e \), we can rewrite as \( z = -\beta_e \text{sgn}[(L_i \otimes I_p)x] + s \), where we know that \( (L_i \otimes I_p)x \) and \( s \) are bounded. Hence it is easy to see that \( z \) will remain bounded. Also \( z \) will be bounded because \( z_i, (L_i \otimes I_p)x \) and \( s \) are bounded. Now, using (13) and under assumptions (P1) and (P3), it is easy to see that \( \zeta \) is bounded.

Knowing that \( s \) is continuous and bounded, we can use the mean value theorem for nonsmooth functions \( [26] \), where we have

\[
\frac{s(t_1) - s(t_0)}{t_1 - t_0} \in S, \forall t_0, t_1
\]

and \( S \) denotes the set \( \partial s(t) \cup \partial(\hat{s}(t)) \) for \( t \in (t_0, t_1) \). Because \( \zeta \) is bounded for every \( \zeta \in \partial \), we know that there exists a \( \kappa \) such that \( \partial s(t) \leq \kappa, \forall t \). Hence, the members of the set \( S \) are all bounded and we have \( s(t_1) - s(t_0) \leq \kappa(t_1 - t_0), \forall t_0, t_1 \), which shows \( s \) is lipschitz and therefore it is uniformly continuous.

Now, choose \( \rho > 0 \) such that \( B_\rho \subset D \) denotes a closed ball. Define \( \mathcal{M} \subset D \) as \( \mathcal{M} \triangleq \{ w \subset \mathcal{M}, W_2(w) \leq \rho \} \)
min $W_1(\varpi) = \lambda_1 \rho^2$. Then, all conditions in Corollary 2.1 LaSalle-Yoshizawa for nonsmooth systems, are provided and we have $W(y) \to 0$ as $t \to \infty$, $\forall y(0) \in \mathcal{M}$. Because $\rho$ can be selected arbitrarily large to include all initial conditions, the region of attraction is $\mathcal{M} = \mathbb{R}^{N(3p+3\nu)}$.

Now, having $W(y) \to 0$, it follows that $s \to 0$, $v_d - \Phi \to 0$ and $(L \otimes I_p)x \to 0$. Since $v_d - \Phi \to 0$, we will have
\begin{equation}
\dot{x}_d = -\beta_3 \mathrm{sgn}[(L_d \otimes I_p)x] - (x_d - r_d) + v_d^r + \epsilon_d,
\end{equation}
where $\epsilon_d \to 0$ as $t \to \infty$. Also using (16), and because $s \to 0$, we have
\begin{equation}
\dot{x}_e = -\beta_3 \mathrm{sgn}[(L_e \otimes I_p)x] - (x_e - r_e) + v_e^r + \epsilon_e,
\end{equation}
where $\epsilon_e \to 0$ as $t \to \infty$. Hence, it turns out that using (11), (18) and (19), we have
\begin{equation}
\dot{\epsilon} = -\beta_3 \mathrm{sgn}[(L \otimes I_p)x] - (x - r) + v^r + \epsilon,
\end{equation}
where $\epsilon$ denotes the Lyapunov candidate function
\begin{equation}
V_1 = x^T(L \otimes I_p)x,
\end{equation}
where its time-derivative along the system (23) is
\begin{equation}
\dot{V}_1 = -\beta_3 x^T(L \otimes I_p)\mathrm{sgn}[(L \otimes I_p)x - x^T(L \otimes I_p)x + x^T(L \otimes I_p)(r + v^r) + x^T(L \otimes I_p)\epsilon
\leq -\beta \Vert (L \otimes I_p)x \Vert_1 - x^T(L \otimes I_p)x + x^T(L \otimes I_p)(r + v^r) + x^T(L \otimes I_p)\epsilon
\end{equation}
Now, by selecting $\min_{i \in \mathcal{I}} \beta_i > \bar{r} + \bar{v}$ and knowing that $\epsilon \to 0$ as $t \to \infty$, we can employ Lemma 2.19 in [27]. As a result we can show that the agents’ positions reach consensus, i.e., $x_i \to x_j$ as $t \to \infty$. Define the variable $S_1 = (1_N \otimes I_p)(x - r) = \sum_{i=1}^{N} x_i - \sum_{i=1}^{N} r_i$, then we can rewrite (23) as
\begin{equation}
\dot{S}_1 = - (1_N \otimes I_p) \beta \mathrm{sgn}(Lx) - S_1 + \epsilon.
\end{equation}
Then we can use input-to-state stability to analyze the system (25) by treating the term $(1_N \otimes I_p)\beta \mathrm{sgn}(Lx)$ as the input and $S_1$ as the state. The system (25) with zero input is exponentially stable and hence input-to-state stable. Since $Lx \to 0$ as $t \to \infty$ for each agent, it follows that $S_1 \to 0$ as $t \to \infty$. This implies that $\sum_{i=1}^{N} x_i \to \sum_{i=1}^{N} r_i$, where combining it with the consensus result, we will have
\begin{equation}
x_i \to \frac{1}{N} \sum_{j=1}^{N} r_j, \quad \forall i \in \mathcal{I}.
\end{equation}

Remark 3.4: Note that the controllers in (8)-(10) are proposed precisely for our heterogeneous framework and they are not just a simple combination of the controllers in the literature. The interaction among agents with different dynamics is one of the challenges that we have faced. The only common state among our agents is position; hence we cannot use the well-known algorithms for double-integrator or Euler-Lagrange dynamics, which they require velocity measurement or communication. It is worthwhile to mention that algorithm (9) is proposed based on the intuition behind Backstepping approach.

**B. Estimator Based Distributed Average Tracking for Heterogeneous Physical Agents**

In this subsection, we propose an estimator based algorithm to address the distributed average tracking problem (7) for heterogeneous multi-agent systems (3)-(5). Here, a filter is used to generate the average of the inputs in a distributed manner, where each agent tracks its own generated signal. In some frameworks, the estimator based algorithm is able to relax the restrictive assumptions mentioned in Subsection III-A. As a trade-off, the estimator based algorithm necessitates communication between neighbors.

First, a filter is introduced for each agent to estimate the average of the reference inputs and reference velocities. Then the control input $u_i$, $i = 1, \ldots, N$, is designed for each agent such that $x_i$ tracks $p_i$, where $p_i \in \mathbb{R}^p$ is the filter’s output. The filter, adapted from [17], is proposed as following
\begin{equation}
\dot{\hat{p}}_i = \hat{q}_i,
\end{equation}
\begin{equation}
\dot{\hat{q}}_i = -\beta_3 \mathrm{sgn} \left[ \sum_{j=1}^{N} a_{ij} \{(p_i + q_i) - (p_j + q_j)\} \right] - \kappa(p_i - r_i) - \kappa(q_i - v^r_i) + \alpha_i, \quad i = 1, \ldots, N
\end{equation}
where $\beta_i = \eta_i \Vert r_i \Vert_1 + \eta_i \Vert v^r_i \Vert_1 + \Vert a^r_i \Vert_1 + \gamma$ is a state based gain and $\eta_i, \gamma$ and $\kappa$ are positive constants to be designed. The controllers are given by
\begin{equation}
u_i = -\eta_i \mathrm{sgn}(x_i - p_i) + q_i, \quad i = 1, \ldots, M, 1
\end{equation}
for agents with single-integrator dynamics and
\begin{equation}
u_i = -\eta_i [x_i - p_i] + (v_i - q_i)] - \eta_i (x_i - p_i) - \eta_i (v_i - q_i) + \hat{q}_i, \quad i = M, \ldots, N', 1
\end{equation}
for agents with double-integrator dynamics and
\begin{equation}
u_i = Y_i(x_i, \dot{x}_i, \dot{p}_i, q_i, \hat{q}_i) \hat{\theta}_i - \alpha_i, \quad i = N', \ldots, N
\end{equation}
\begin{equation}s_i = \mu(x_i - p_i) + (\dot{x}_i - q_i),
\end{equation}
\begin{equation}\dot{\hat{\theta}}_i = -Y_i(x_i, \dot{x}_i, \dot{p}_i, q_i, \hat{q}_i)^T s_i,
\end{equation}
for agents with Euler-Lagrange dynamics, where $\alpha$ and $\mu$ are positive constants.

**Theorem 3.5:** Under the control law given by (27)-(30) for the system defined in (3)-(5), the distributed average tracking goal (7) is achieved asymptotically, provided that Assumptions 3.1 and 3.2 hold and the control gains are chosen such that $\eta_i > \kappa > 1$ and $\gamma, \alpha$ and $\mu$ are positive constants.
Proof: Filter: Here, it is proved that, \( \forall i = 1, \ldots, N \), we have
\[
\lim_{t \to \infty} p_i = \frac{1}{N} \sum_{j=1}^{N} r_{ij} \quad \lim_{t \to \infty} q_i = \frac{1}{N} \sum_{j=1}^{N} v_{ij}^r.
\]

Let \( p = [p_1^T, \ldots, p_N^T]^T \) and \( q = [q_1^T, \ldots, q_N^T]^T \), denote the aggregated states of the filters. Let \( M = I_N - \frac{1}{N} I_N \). Note that \( M \) has one simple zero eigenvalue with \( I_N \) as its right eigenvector and has 1 as its other eigenvalue with the multiplicity \( N - 1 \). Define the consensus error vectors \( \tilde{p} = (M \otimes I_p)p \) and \( \tilde{q} = (M \otimes I_p)q \). Then it is easy to see that \( \tilde{p} = 0 \) (respectively, \( \tilde{q} = 0 \)) if and only if \( p_i = p_j, \forall i, j \in I \).\( (q_i = q_j, \forall i, j \in I) \).

Now, the estimator dynamics (27) can be rewritten in vector form as
\[
\dot{\tilde{p}} = \tilde{q},
\]
\[
\dot{\tilde{q}} = -\alpha (M \otimes I_p) \text{sgn}([L \otimes I_p]p + \tilde{q}) - \kappa \tilde{p}
+ \kappa (M \otimes I_p)r - \kappa \tilde{q} + \kappa (M \otimes I_p)v^r + (M \otimes I_p)\alpha^r
\]
where \( r(t) = [r_1^T, \ldots, r_N^T]^T \), \( v^r(t) = [v_{1r}^T, \ldots, v_{N^r}^T]^T \) and \( \alpha^r(t) = [\alpha_{1r}^T, \ldots, \alpha_{N^r}^T]^T \), are respectively, the aggregated reference inputs, reference velocities and reference accelerations, and \( \beta = \text{diag}(\beta_1, \ldots, \beta_N) \).

Consider the Lyapunov function candidate \( V_1 = \frac{1}{2} \left[ \tilde{p}^T \left( L \otimes \begin{bmatrix} 2\alpha & 0 \\ 0 & 1 \end{bmatrix} \otimes I_N \right) \tilde{p} \right] + \frac{1}{2} \left[ \tilde{q}^T \left( L \otimes \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \otimes I_N \right) \tilde{q} \right] \). Since \( (1_N \otimes I_p)^T \tilde{p} = 0_{N^p} \) and \( (1_N \otimes I_p)^T \tilde{q} = 0_{N^q} \), by using Lemma 2.1, we have \( V_1 \geq \frac{\lambda_2(L)}{2} \left[ \tilde{p}^T \left( L \otimes \begin{bmatrix} 2\alpha & 0 \\ 0 & 1 \end{bmatrix} \otimes I_N \right) \tilde{p} \right] + \frac{1}{2} \left[ \tilde{q}^T \left( L \otimes \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \otimes I_N \right) \tilde{q} \right] \), where \( \lambda_2(L) \) is defined in Lemma 2.1. Now, using the fact that
\[
\begin{bmatrix}
2\alpha & 1 \\
1 & 1
\end{bmatrix} > 0,
\]
for \( \kappa > \frac{1}{2} \), it is easy to see that \( V_1 \) is positive definite. The derivative of \( V_1 \) is given as
\[
\dot{V}_1 = 2\kappa \tilde{p}^T \left( L \otimes I_p \right) \tilde{q} + \tilde{q}^T \left( L \otimes I_p \right) \tilde{p} - \kappa \tilde{p}^T \left( L \otimes I_p \right) \tilde{p} + \tilde{q}^T \left( L \otimes I_p \right) \tilde{q} - \kappa \tilde{q}^T \left( L \otimes I_p \right) \tilde{q} - \kappa \tilde{q}^T \left( L \otimes I_p \right) \tilde{q} + \kappa \tilde{p}^T \left( L \otimes I_p \right) \tilde{q} + \kappa \tilde{q}^T \left( L \otimes I_p \right) \tilde{p} - \kappa \tilde{q}^T \left( L \otimes I_p \right) \tilde{q} + \kappa \tilde{p}^T \left( L \otimes I_p \right) \tilde{q} - \kappa \tilde{p}^T \left( L \otimes I_p \right) \tilde{q} \]
where we have used \( LM = L \). Now using the triangular inequality, we have
\[
\dot{V}_1 \leq -\kappa \tilde{p}^T \left( L \otimes I_p \right) \tilde{p} - \kappa \tilde{q}^T \left( L \otimes I_p \right) \tilde{q}
+ \sum_{i=1}^{N} \parallel \sum_{j=1}^{N} a_{ij} \left\{ \tilde{p}_i + \tilde{q}_j \right\} \parallel_1 \times 
(\kappa \parallel r_i \parallel_1 + \kappa \parallel v_{ij}^r \parallel_1 + \parallel a_{ij}^r \parallel_1) \]
\[
- \frac{1}{N} \sum_{i=1}^{N} \beta_i \parallel \sum_{j=1}^{N} a_{ij} \left\{ \tilde{p}_i + \tilde{q}_j \right\} \parallel_1 \times 
\left\{ \sum_{j=1}^{N} a_{ij} \left\{ \tilde{p}_i + \tilde{q}_j \right\} - \left\{ \tilde{p}_j + \tilde{q}_j \right\} \right\}_1.
\]

Now, using a procedure similar to proof of Theorem 5.3, the variables \( S_1 = \sum_{i=1}^{N} (p_i - r_i) \) and \( S_2 = \sum_{i=1}^{N} (q_i - v_{ij}^r) \) are defined. By summing both sides of (27), for \( i = 1, \ldots, N \) we have
\[
\dot{S}_1 = S_2,
\]
\[
\dot{S}_2 = -\kappa S_1 - \kappa S_2 - \sum_{i=1}^{N} \beta_i \text{sgn} \left\{ \sum_{j=1}^{N} a_{ij} \left\{ (p_i + q_i) - (p_j + q_j) \right\} \right\}.
\]

Then we can use input-to-state stability to analyze the system (33) by treating the term \( \sum_{i=1}^{N} \beta_i \text{sgn} \left\{ \sum_{j=1}^{N} a_{ij} \left\{ (p_i + q_i) - (p_j + q_j) \right\} \right\} \) as the input and \( S_1 \) and \( S_2 \) as the states. Since \( \kappa > 1 \), the matrix \( \begin{bmatrix} 0 & I_p \\ -\kappa I_p & -\kappa I_p \end{bmatrix} \) is Hurwitz. Thus, the system (33) with zero input is exponentially stable and hence input-to-state stable and we have \( S_1 \to 0 \) and \( S_2 \to 0 \). Therefore, we have that \( \lim_{t \to \infty} \sum_{i=1}^{N} p_i = \sum_{i=1}^{N} r_i \) and \( \lim_{t \to \infty} \sum_{i=1}^{N} q_i = \sum_{i=1}^{N} v_{ij}^r \). Now, using (32), it is easy to see that the estimation goal (31) is achieved.
Controller: Here, each agent tracks its own generated signal, its own estimator output, where it is shown that by using the control inputs (28)-(30), we have \( \lim_{t \to \infty} x_i = p_i \) for \( i = 1, \ldots, N \).

Single-integrator: Using the control input (28) for (3), we obtain the closed-loop dynamics for agents with single-integrator dynamics as

\[
\dot{x}_i = -\eta_i \text{sgn}(\dot{x}_i), \quad i = 1, \ldots, M - 1,
\]

where \( \dot{x}_i = x_i - p_i \). Consider the candidate Lyapunov function \( V_s = \frac{1}{2} \dot{x}_i^2 \). By taking the derivative of \( V_s \), we have

\[
\dot{V}_s = -\eta_i \| \dot{x}_i \|_1.
\]

It is now easy to conclude that \( \dot{x}_i \), for \( i = 1, \ldots, M - 1 \), converges to zero.

Double-integrator: For agents with double-integrator dynamic the closed-loop system, using the control input (29) for (4), can be written as

\[
\dot{v}_i = -\eta_i \text{sgn}(\dot{x}_i + \dot{v}_i) - \eta_i \ddot{x}_i - \eta_i \dddot{v}_i, \quad i = M, \ldots, N' - 1,
\]

where \( \dot{v}_i = v_i - q_i \). Consider the candidate Lyapunov function

\[
V_d = \frac{1}{2} \left[ \dot{x}_i^T \ddot{x}_i \right]^T \left[ 2\eta_i I_p \right] \dot{x}_i + \frac{1}{2} \dot{v}_i^T \dddot{v}_i. \]

Since \( \eta_i > \frac{1}{3} \), \( V_d \) is positive definite. The derivative of \( V_d \) along system (53) is obtained as

\[
\dot{V}_d = 2\eta_i \dot{x}_i^T \ddot{x}_i + \dot{v}_i^T \dddot{v}_i - \eta_i \dddot{x}_i^T (\dot{x}_i + \dot{v}_i)
- \eta_i \dddot{x}_i \text{sgn}(\dot{x}_i + \dot{v}_i) - \eta_i \dddot{v}_i (\dot{x}_i + \dot{v}_i) - \eta_i \dddot{v}_i \text{sgn}(\dot{x}_i + \dot{v}_i)
= -\eta_i \dot{x}_i^T \ddot{x}_i + (1 - \eta_i) \dddot{v}_i^T \dddot{v}_i - \eta_i \| \dot{x}_i + \dot{v}_i \|_1.
\]

Since \( \eta_i > 1 \), it is concluded that \( \| \dot{x}_i \| \) for \( i = M, \ldots, N' - 1 \), asymptotically converges to zero.

Euler-Lagrange: It follows form (P3) and (50) that the closed-loop dynamics for agent \( i = N', \ldots, N \), can be written as

\[
M_i(x_i)\dddot{x}_i + C_i(x_i, \dot{x}_i)\dot{x}_i + Y_i(x_i, \dot{x}_i, p_i, q_i, \dot{q}_i)\theta_i = 0
\]

where using the boundedness of its components, we can see that \( Y_i(x_i, \dot{x}_i, p_i, q_i, \dot{q}_i) \) is bounded for \( i = N', \ldots, N \). Now, it follows form (36) that \( \dot{s}_i \) is bounded. This guarantees the boundedness of \( V_c \). Thus by using Lyapunov-like lemma, we have \( s_i \to 0 \) for \( i = N', \ldots, N \). Using an argument similar to Lemma 5 in (28), it is obtained that \( \lim_{t \to \infty} x_i = p_i \) for \( i = N', \ldots, N \). Till now it is proved that \( \lim_{t \to \infty} x_i = p_i \) for \( i = 1, \ldots, N \). Now, it follows from (51) that the goal (7) is achieved.

Remark 3.6: Note that the restriction in Theorem 3.5 Assumption [3.2] is placed by agents with Euler-Lagrange dynamic. As it is stated in P3, the regression matrix \( Y_i \) is a function of its own states, \( x_i \) and \( \dot{x}_i \). According to our goal, these states have to track, respectively, the average of the reference inputs and the reference velocities; hence to guarantee a bounded \( Y_i \), it is required to have a bounded reference input and the reference velocity (Assumption 3.2).

Remark 3.7: Both algorithms introduced in (8)-(10) and (27)-(30) require that Assumptions 3.2 hold. In algorithm (8)-(10), the agents just need their own positions and the relative positions between themselves and their neighbors. In some applications, these pieces of information can be obtained by sensing; hence the communication necessity might be eliminated. However, in algorithm (27)-(30), each agent must communicate two variables \( p_i \) and \( q_i \) with its neighbors, which needs communication.

Remark 3.8: The restriction noted in Remark 3.6 is inevitable when we have an agent with Euler-Lagrange dynamics among our agents. However, for a multi-agent system consisting of agents with only single-integrator and double-integrator dynamics, Assumption [3.2] will be relaxed in algorithm (27)-(30). As a result, there will be no restriction on admissible reference inputs. Note that in this framework Assumptions 3.2 can not be relaxed for algorithm (8)-(10).

IV. SIMULATION AND DISCUSSION

In this section, we present a simulation to illustrate the theoretical result in Subsection III-A. Consider a team of six agents. The interaction among the agents is described by an undirected graph shown in Fig. 1, where agents are colored based on their dynamics. Agents with single-integrator, double-integrator, and Euler-Lagrange dynamics are, respectively, colored red, blue, and green.

The agents’ goal is to track the average of their reference inputs. The reference input for agent \( i \) is defined as \( r_i(t) = \frac{3\sin(\frac{\pi}{2} t)}{4\cos(\frac{\pi}{2} t)} \). The reference input and its velocity is bounded and Assumption [3.2] is satisfied. The dynamic for agents with single-integrator and double-integrator dynamics is defined as (3) and (4). The dynamic equation for each Euler-Lagrange agent is modeled by \( m_i \ddot{x}_i + c_i \dot{x}_i = u_i, i = 5, 6 \), where \( x_i(t) \) is the coordinate of agent \( i \) in 2D plane (29). The parameters \( m_i \) and \( c_i \) represent, respectively, the mass and damping constants of the agent \( i \), which are assumed to be constant but unknown.

We let \( m_1 = 1, c_1 = 0.5, m_2 = 1.5 \), and \( c_2 = 0.6 \).
In our example, we apply the algorithm (8)-(10), where the controllers’ parameters are selected as $\beta_i = 25, \forall i \in \mathcal{I}$, and $\alpha = 15$. The initial positions of the agents are selected as $[8 0]^T$, $[9 3]^T$, $[10 6]^T$, $[11 9]^T$, $[12 12]^T$, and $[13 15]^T$ and their initial velocities are selected as zero. Fig. 2 shows that the distributed average tracking is achieved and agents track the average of the reference inputs.

V. CONCLUSIONS

In this paper, a distributed average tracking was studied for a group of heterogeneous physical agents. The multi-agent system was consisted of the agents with single-integrator, double-integrator and Euler-Lagrange dynamics. Two nonsmooth algorithms were proposed to achieve the distributed average tracking goal. In our first proposed algorithm, each agent required to have access to only its own position and the relative positions between itself and its neighbors, where it was possible to rely on only local sensing. To relax some restrictive assumptions on admissible reference inputs, we proposed the second algorithm, where a filter was introduced for each agent to generate an estimation of the average reference inputs. Then, each agent tracked its own generated signal.
