Temperature and magnetic field dependence of superconductivity in nanoscopic metallic grains

Abstract

We study pairing correlations in ultrasmall superconductor in the nanoscopic limit by means of a toy model where electrons are confined in a single, multiply degenerate energy level. We solve the model exactly to investigate the temperature and magnetic field dependence of number parity effect (dependence of ground state energy on evenness or oddness of the number of electrons). We find a different parity effect parameter to critical temperature ratio (∼4 rather than 3.5) which turns out to be consistent with exact solution of the BCS gap equation for our model. This suggest the equivalence between the parity effect parameter and the superconducting gap. We also find that magnetic field is suppressed as temperature increases.

Single electron tunnelling experiments of Ralph, Black and Tinkham (RBT) initiated interest on the possibility of superconductivity in a nanometer size Al grain. Although existence of superconductivity in a very small metallic particle has been discussed long time ago, it has been possible to investigate such small systems only recently with experiments of RBT. Anderson’s criterion, that superconductivity ceases when discrete energy level spacing becomes comparable with superconducting gap is correct in general, should be treated carefully at such small scales.

Instead of macroscopic properties like zero resistance and Meissner effect, superconductivity in nanometer size metallic grain manifests itself as an odd-even or number parity effect, i.e. dependence of physical properties on whether grain has odd or even number of electrons in it. Evaluation of discrete energy spectrum using BCS model or exact diagonalization of finite systems has been the main subject of theoretical studies. (For a review see Ref. 8).

For parabolic energy dispersion, which is the case for a grain with perfect symmetry, discrete energy levels are multiply degenerate. Figure 25.1 of Ref. 9 and Fig. 1 of Ref. 11 show explicitly that for parabolic dispersion degeneracy of energy levels can be very large. For example, the number of solutions satisfying

\[ n^2 = n_1^2 + n_2^2 + n_3^2, \]

all being integer, can approach to 40 for \( n \leq 100 \). Although disorder and irregular shape split the degeneracy, as long as they are weak, we can still talk about near degeneracy. The main point is that typical scale of dimensional energy quantization \( \delta_1 = \hbar \nu_F / L \) is, \( L \) being the size of the grain, much larger than level spacing \( \delta_2 \sim E_F / N \), where \( E_F \) is fermi energy and \( N \) is the total number of electrons, even for disordered samples. If attractive electron-electron interaction is much less than \( \delta_1 \), but yet larger than \( \delta_2 \), we can approximate the system as a single, multiply degenerate energy level provided that disorder is not too strong. A single energy level is certainly drastic approximation. Our aim is to find out possibility of superconductivity, or pairing correlations, in this extreme limit. Physical systems are probably between bulk BCS model and the nanoscopic (or quantum) limit. By examining the behavior of a superconductor at both ends we expect to figure out properties of real systems. Finally, our earlier works show that exact solution of multi-level model agrees very well with single energy level model in the large level spacing (or nanoscopic) limit. The formula, obtained in the single level approximation, for the ratio of the number parity effect parameters for odd and even cases gives results within one percent neighborhood of the exact solution when level spacing is about ten times larger than the superconducting energy gap.

Our starting point is a single, multiply degenerate energy level. We consider \( d \) states and assume that electrons in the same state are paired. Therefore the model Hamiltonian becomes

\[
H = -g \sum_{n,n'=1}^{d} a_{n \uparrow}^\dagger a_{n' \downarrow}^\dagger a_{n \downarrow} a_{n' \uparrow}, \tag{1}
\]

where \( a_{n \sigma}^\dagger (a_{n \sigma}) \) creates (annihilates) an electron in state \( n \) with spin \( \sigma \). Such a model has already been used long time ago by Mottelson to study pairing of nucleons. In our case \( n \) describes a state where time-reversed partner is itself. Hence, we assume that electrons occupying the same state are paired and they can be scattered into anyone of the unoccupied states together with the same amplitude. It is an immediate consequence of the form of the interaction that singly occupied states give vanishing matrix elements. Single electrons
simply block a state from any scattering event. Therefore, their mere effect is to eliminate
certain states in the Hamiltonian. On the other hand, doubly occupied and empty states can
be denoted in pseudo-spin representation which allows us to diagonalize the Hamiltonian
easily.

Pseudo-spins $s$ are introduced by the definition $s_{n+} = a_{n\uparrow}^\dagger a_{n\downarrow}$ and $s_{n-} = \frac{1}{2}(a_{n\uparrow}^\dagger a_{n\uparrow} + a_{n\downarrow}^\dagger a_{n\downarrow} - 1)$ which allows us to write the Hamiltonian as $H = -gS_z S_- + S_+ S_-$ where $S = \sum_n s_n$ is
the total spin and $S_\pm$ are corresponding raising and lowering operators. Finally, when it is
written as $H = -g(S^2 - S_z^2 + S_z)$, we obtain energy eigenvalues as

$$E(s) = -\frac{g}{4}(N - s)(2d - s - N + 2)$$

where

$$s = \begin{cases}
0, 2, 4, \ldots, 2d - N, \ldots, N & \text{for } N \text{ even} \\
1, 3, 5, \ldots, 2d - N, \ldots, N & \text{for } N \text{ odd}.
\end{cases}$$

Here, seniority number $s = d - 2S$ has been introduced to simplify the expressions. We
note that for a given number of electrons $N$, $z$-component $S_z$ of the pseudo-spin is fixed and
hence eigenvalues are labelled by only one quantum number $S$. Degeneracy of each $S$, i.e.
several different ways of obtaining the same total spin value, makes the problem nontrivial.
Therefore, we have to find the total number of states $\Omega(s)$ having the same seniority
number $s$ to evaluate thermodynamical quantities. Let us start with the ground state which
corresponds to the largest possible total spin $S$ or equivalently the smallest possible seniority
$s$. For even $N$, $s = 0$ state is unique whereas for odd $N$, due to un-paired electron there is
2d-fold degeneracy. Here, we assume that the grain interacts with a heat bath where spin
flip is possible which gives the factor 2.

Next, we consider the excited states which can be created not only by pair breaking
(single particle excitations) but also by changing total spin value with fixed number of
pairs (collective excitations). Single particle and collective excitations turn out to have the
same energy spectrum. Hence, the total degeneracy $\Omega(s)$ can be obtained by summation
degeneracies of each configuration. Contribution of un-paired electrons to degeneracy is
nothing but the number of combinations of $d$ states taken $s$ at a time. Including spin degree
of freedom results in a factor $2^s$. Different ways of obtaining the same total spin $S$ with $N$
spin-1/2 particles, which is given by

$$\binom{N}{N/2 - S} - \binom{N}{N/2 - S - 1},$$

brings an additional contribution. Total degeneracy is found by proper use of the two
formulae. Summation over all possible configurations having the same seniority gives us the
total degeneracy

$$\Omega(s) = \sum_{i=0}^{I} \left[ \binom{d - s + 2i}{i} - \binom{d - s + 2i}{i - 1} \right] \binom{d}{s - 2i} 2^{s-2i}$$

where $I$ is equal to $\frac{s}{2} , \frac{(s-1)}{2}$ for even $N$ and odd $N$, respectively.
Before going to evaluate thermodynamical quantities let us calculate the ground state energy as a function of number of electrons \( N \), for a given degeneracy \( d \). Figure 1 shows \( d = 20 \) case. For \( N = 20 \), the level is half-filled and we reach the minimum. This is an expected result since both the number of pairs and the number of the empty states into which they scatter are maximized to have the optimum energy. Zig-zag structure of the curve is due to the parity effect. When \( N \) is odd there is a unpaired electron which is neither scattered out and nor allows any pair to be scattered into the state it occupies. This blocking effect effectively decreases the number of states by one.

Noting the fact that Zeeman energy shifts of discrete levels are much more important than orbital diamagnetism\(^0\) we can immediately write down energy eigenvalues in the presence of a uniform magnetic field as

\[
E_H = E_{H=0} - \mu_B H (n_{\uparrow} - n_{\downarrow}),
\]

(6)

where \( n_{\uparrow} \) and \( n_{\downarrow} \) denote the number of spin-up and spin-down electrons, respectively. Although, we find \( E_H \) easily, degeneracy expression is no more simple but instead changes with magnetic field. However, for small number of states it is not difficult to count the energy levels to find degeneracy of each energy eigenvalue.

Having degeneracy of each state we can evaluate specific heat \( C_v = \frac{\partial \langle E \rangle}{\partial T} \) as a function of temperature where

\[
\langle E \rangle = \frac{\sum_s E(s)\Omega(s)e^{-E(s)/kT}}{\sum_s \Omega(s)e^{-E(s)/kT}}.
\]

(7)

Observation of specific heat variation is one of the most direct ways to find critical temperature \( T_c \) and magnetic field \( H_c \).

Figure 2 shows variation of \( C_v(T) \) with temperature for different number of electrons. Discontinuity in the specific heat, which is a indication of a second order phase transition in macroscopic systems, now manifests itself as a relatively fast variation in \( C_v(T) \) curve. Absence of a sharp change results in ambiguity in determination of \( T_c \). We are going to identify the temperature at which the maximum of \( C_v(T) \) curve is reached as \( T_c \). We note that the linear background, i.e. contribution to \( C_v(T) \) which is of the form const.\( T \), is absent. This is because linear term is a result of Fermi-Dirac distribution and continuous spectrum near Fermi energy. Since in our case, we have a single level, \( C_v(T) \) curve has a flat background.

In Fig. 3 we plot critical temperature for different magnetic fields as a function of number of electrons. Higher value of \( T_c \) for even number of electrons is an indication of number parity effect which can be defined as

\[
\Delta_P = \left| E^{2N+1} - \frac{E^{2N} + E^{2N+2}}{2} \right|
\]

(8)

where \( E^{2N} \) is the ground state energy for \( 2N \) electrons. \( \Delta_P \) has no \( N \) label because for our model it can be shown that \( \Delta_P = gd/2 \), independent of \( N \). However, at finite temperature \( \Delta_P \) should be redefined. One possibility is to replace ground state energies by thermal averages where we obtain \( \Delta_P(T) \) as a decreasing function of temperature\(^2\). We note that for \( H = 0 \), \( kT_c/g \simeq 2 \) while \( \Delta_P/g = 5 \) which gives \( 2\Delta_P/kT_c = 5 \). With increasing \( d \) we
observe that ratio decreases. For $d = 100$, which is not plotted due to invisibility small odd-even dependence, $2\Delta_P/kT_c = 4.6$. Here the interesting point is that BCS gap equation

$$
\Delta_k = -\sum_l V_{kl} \frac{\Delta_l}{2E_l} \tanh \frac{E_l}{2kT}
$$

(9)

can be solved analytically, with $V_{kl} = -g$, $E_k = E$ and $\Delta_k = \Delta$, to give $kT_c/g = d/4 = \Delta_0/2g$, and we find $2\Delta_0/kT_c = 4$ (rather than 3.5).

Finally, in Fig. 4, we plot critical magnetic as a function of temperature. We attribute the feature at low temperatures to slightly ambiguity in the definition of critical temperature. In interpreting $H_c(T)$ curve we should keep in the mind that the critical magnetic field is determined by Zeeman splitting. For a different geometry, for example for a ring shaped conductor, orbital coupling can also play an important role.

In conclusion, we can understand basic physics of thermal and magnetic properties of a nanoscopic superconductor using our very simple model which can be solved exactly. In the extreme nanoscopic limit where a single degenerate or nearly degenerate energy level is left we predict a different gap to critical temperature ratio. Our results, with increasing number of levels, approach to exact solution of the BCS gap equation which gives $2\Delta_0/kT_c = 4$ (rather than 3.5). This suggest the equivalence between the parity effect parameter $\Delta_P$ and the superconducting gap $\Delta$. Finally, we observe that the critical magnetic field is suppressed with increasing temperature.
