Abstract

Percutaneous nephrolithotomy (PCNL) has proven very effective in the management of renal stones. However, complications are not so rare, and bleeding is one of the most worrisome; it has a reported incidence of 1%–3% and may happen during track dilatation. In addition, arterial pseudoaneurysms and/or arteriovenous fistulas (AVF) may occur. We report the case of a patient with an intrarenal pseudoaneurysm associated with an AVF, after PCNL. Superselective endovascular embolization with Onyx® was successfully performed, achieving exclusion of the pseudoaneurysm and AVF with preservation of the remaining vascularization of the kidney. We review the literature regarding endovascular management of kidney vascular lesions after PCNL. Selective renal embolization is a minimally invasive procedure, highly effective with a low incidence of complications. Currently, it is considered the most appropriate technique in the treatment of arterial iatrogenic complications following percutaneous renal procedures. Onyx® is an effective, easy to handle, and safe alternative embolic agent for these procedures.

Keywords: Arterial pseudoaneurysm, arteriovenous fistula, endovascular treatment, onyx, percutaneous nephrolithotomy

INTRODUCTION

Percutaneous nephrolithotomy (PCNL) has proven very effective in the management of renal stones. However, complications rate after PCNL is in the range of 20%–83%. Major bleeding requiring intervention has a reported incidence of 1%–3% in large series.¹⁻⁴ In addition, arterial pseudoaneurysms, arteriovenous fistulas (AVF), and arteriocalceal fistulas may occur, with a reported incidence of 0.9%–2%, 0.2%–1.5%, and 0.3%, respectively.

In 24%–36% of the cases with pseudoaneurysms, there is also an AVF associated.²⁻³

Bleeding after PCNL is mainly controlled with conservative treatment options. If it does not cease spontaneously, it can cause gross hematuria or even life-threatening hemorrhage, requiring prompt treatment by transarterial embolization (TAE). Endovascular treatment is recommended in these cases due to its effectiveness and low complications rate.⁶

We report our experience with TAE of a renal pseudoaneurysm and AVF after PCNL, using Onyx® as the primary embolic agent.

CASE REPORT

A 68-year-old male treated with a standard PCNL for a 30 mm inferior caliceal stone in the right kidney, using an intracorporeal ultrasonic lithotripter, started complaining of intermittent hematuria after being discharged home. Thirteen days later, he had an episode of urinary retention that led him back to the hospital. Blood tests showed a drop in hemoglobin level (14.6–11.9 mg/dL) and normal renal function. Initial ultrasound (US) documented hydronephrosis, multiple clots in the right renal pelvis and bladder. A Foley catheter was placed confirming macroscopic hematuria, irrigation and washout procedures were started. A contrast-enhanced computed tomography (CT) revealed a pseudoaneurysm of a segmental artery in the PCNL “track” [Figures 1 and 2]; additionally, the CT confirmed the US findings and showed a double-J stent incorrectly positioned and a residual 6 mm stone. The patient was initially managed conservatively. Ureterorenoscopy was performed for blood clot evacuation and repositioning of a double-J stent. Following the intervention there was a further drop of hemoglobin (8.1 mg/dL), blood transfusions were required, and the patient was referred for digital subtraction angiography (DSA).

Selective renal angiography was performed, through right retrograde femoral access, using a 5F vascular sheath and a 5F cobra catheter advanced over a hydrophilic 0.035 inch guidewire. A 2.7F coaxial microcatheter was advanced, over 0.021 inch guidewire, enabling superselective approach of the feeding artery, confirming a pseudoaneurysm originating from an inferior pole branch and further documenting an AVF [Figures 3 and 4]. To perform embolization, 0.6 mL of dimethyl sulfoxide (DMSO) were injected to fill the microcatheter’s dead space, followed by 0.8 mL of Onyx18®, at a rate of approximately 0.1 mL/min, under fluoroscopic control. Exclusion of the pseudoaneurysm and the AV fistula was successfully achieved, with preservation of the remaining vascularization of the right kidney and no evident parenchymal loss [Figures 5 and 6]. Doppler US was performed in the angiosuite before and after the procedure confirming the findings [Figure 7]. Total procedure time was 40 min; no immediate complications were registered and hematuria disappeared 3 days later. The patient remained asymptomatic, and no relapse was found at 3-month CT follow-up.

DISCUSSION

Symptoms of bleeding after PCNL may present within the first 24 hours or as far as 20 days, although the mean time to the onset varies between 6 and 8 days in large series.[2-8] Noninvasive diagnostic modalities, US and CT, should be included in the initial work-up, but DSA remains the gold standard.[9] When PCNL complicates with bleeding that cannot be controlled with conservative treatment, DSA is used both as a diagnostic and therapeutic modality. DSA should be considered in case of gross hematuria-related tachycardia, a serum haemoglobin level <10 g/dL, and hypotension resulting in hemodynamic instability and requiring blood transfusions.[3] The most common angiographic findings associated with hemorrhage after PCNL are arterial pseudoaneurysms and/or AVF; less
often arteriocaliceal fistulas, lumbar artery injury or active hemorrhage may also be found.2-5 The lesions responsible for hematuria are believed to happen after trauma, during track dilatation and are nearly always located in segmental arteries, which supply a small portion of the kidney that can be embolized.4,10 The lacerated artery is a high-pressure system and will leak into the lower pressure system of a vein leading to AVF formation or the parenchyma or hilar areolar tissue leading to pseudoaneurysm formation.2

Selective renal embolization is currently considered the most appropriate technique in the treatment of vascular complications of percutaneous renal procedures, with a success rate >80% and low complications rate.6 Microcatheters are used to allow a superselective approach of the distal segmental branches, minimizing loss of viable tissue.5 Endovascular techniques have a lower complication rate than surgical management. Complications that can develop during TAE are limited and include complications related to femoral arterial puncture; selective catheterization of a vessel; and embolization-related complications, such as nontarget embolization and postembolization syndrome. When AVF is present, there is a possible risk of migration of the embolic agent to the venous system, which may be complicated of pulmonary embolism. Late complications such as vascular recanalization have seldom been reported.5,9

Various embolic agents are available to treat vascular complications of PCNL including coils, particulate agents (e.g., gelfoam) and liquid agents (e.g. Onyx®, n-buty1 cyanoacrylate [n-BCA]). They can be used either alone
or as complementary tools. Onyx® has been used for the endoluminal treatment of vascular cerebral malformations, as a permanent and efficient occluding agent, for several years. However, there are few reports concerning embolization of iatrogenic intrarenal pseudoaneurysm and AFV with Onyx®.[11,12] Onyx® is a biocompatible polymer, ethylene vinyl alcohol copolymer (EVOH), that is dissolved in an organic solvent, DMSO. When it enters in contact with blood, the DMSO rapidly diffuses, leaving the EVOH to precipitate and solidify as a spongy embolus at the tip of the catheter.[11,12] It has a lava-like flow pattern and long solidification time. In addition, the injection can be interrupted and continued again until the desired result is achieved. Therefore, Onyx® can be delivered in a slower, accurate and more controlled way than other embolic agents, reducing significantly the risk of ischemic complications and reflux to the venous component of AVF.[13] Unlike n-BCA, it causes no postprocedural pain, neither catheter adhesion.[9] From a surgical point of view, Onyx® is a suitable preoperative embolic agent, since it is mechanically occlusive but not adherent to the arterial wall.[11]

In conclusion, we performed embolization with Onyx® of an iatrogenic pseudoaneurysm on a segmental arterial renal branch associated with an AVF. It allowed a controlled, fast, painless, safe and effective embolization.
