(Received 13 December 2012; published 22 February 2013)

We show that nearly extremal Kerr black holes have two distinct sets of quasinormal modes, which we call zero-damping modes (ZDMs) and damped modes (DMs). The ZDMs exist for all harmonic indices \( l \) and \( m \geq 0 \), and their frequencies cluster onto the real axis in the extremal limit. The DMs have nonzero damping for all black hole spins; they exist for all counterrotating modes \( (m < 0) \) and for corotating modes with \( 0 \leq \mu \leq \mu_c = 0.74 \) (in the eikonal limit), where \( \mu = m/(l + 1/2) \). When the two families coexist, ZDMs and DMs merge to form a single set of quasinormal modes as the black hole spin decreases. Using the effective potential for perturbations of the Kerr spacetime, we give intuitive explanations for the absence of DMs in certain areas of the spectrum and for the branching of the spectrum into ZDMs and DMs at large spins.

DOI: 10.1103/PhysRevD.87.041502 PACS numbers: 04.25.Nx, 04.70.Bw

I. INTRODUCTION

Nearly extremal Kerr (NEK) black holes (BHs)—i.e., BHs for which the dimensionless angular momentum \( a = 1 \) in the geometrical units, \( G = c = M = 1 \), used in this paper—have drawn much attention recently. Besides the mounting evidence for fast-rotating BHs in astronomy [1], NEK BHs have considerable theoretical significance, for example, in studies of weak cosmic censorship [2] and in the present understanding of the QNM spectrum of NEK BHs is inconclusive.

In a recent paper [15], some of us used a WKB analysis to relate Kerr QNMs in the eikonal limit to spherical photon orbits around Kerr BHs. We pointed out that a subset of spherical photon orbits of extremal Kerr BHs reside on the horizon and that the corresponding QNMs have zero damping. This happens when the parameter \( \mu = m/(l + 1/2) \geq \mu_c \approx 0.74 \). Hod [16] computed \( \mu_c \) in the eikonal limit, finding an approximate analytical result in agreement with Ref. [15].

In this work, we will show that the NEK geometry has two distinct sets of QNMs: zero-damping modes (ZDMs) and damped modes (DMs). ZDMs are associated with the near-horizon geometry of the BH, and they exist for all allowed values of \( l \) and \( m \geq 0 \) (we classify modes using Leaver’s conventions [17], but we use units in which the BH mass \( M = 1 \)). DMs are associated with peaks of the potential barrier; in the eikonal limit, they exist when \( \mu \leq 0.74 \). This implies that ZDMs and DMs coexist if \( 0 \leq \mu \leq 0.74 \). Figure 1 is a “phase diagram” in QNM space, showing the regions where either the ZDMs or both the DMs and the ZDMs exist for scalar and gravitational perturbations with \( l \leq 15 \). We will discuss this phase diagram further below. When the ZDMs and DMs coexist, and when the BH spin \( a \) is small, for each \( (l, m) \) there is only a single set of QNMs characterized by the overtone number \( n \) (where modes with larger \( n \) have stronger damping). For larger \( a \), this set of QNMs appears to break into two branches. The DM branch originates from lower-overtone modes at smaller \( a \), and its modes retain a finite decay rate as \( a \to 1 \). The ZDM branch originates from higher-overtone modes whose imaginary part becomes smaller than that of DMs as \( a \to 1 \), thereby forming the second branch. This is similar to the behavior of eigenmodes in quantum mechanics when we parametrically split a single
FIG. 1 (color online). Phase diagram for the separation between the single- and double-branch regime for NEK BHs. Large purple dots and gold crosses correspond to \((l, m)\) pairs with only ZDMs for perturbations with spin \(-2\) and \(0\), respectively. Smaller blue dots correspond to \((l, m)\) pairs with both ZDMs and DMs. The green line is the phase boundary, computed using the eikonal approximation.

potential well into two potential wells (cf. Fig. 2 above, as well as Ref. [18] for a somewhat analogous phenomenon in the theory of oscillations of ultracompact stars).

II. MATCHED EXPANSIONS

For \(\epsilon \equiv 1 - a \ll 1\) and \(\omega - m/2 \ll 1\), the radial Teukolsky equation can be written in a self-similar form when \((r - 1) \ll 1\) and in an asymptotic form (by setting \(a = 1\)) when \((r - 1) \gg \sqrt{\epsilon}\) (cf. Refs. [9,10,19]). The solutions of the Teukolsky equation in these regions (hypergeometric and confluent hypergeometric functions, respectively) can be matched at \(\sqrt{\epsilon} \ll (r - 1) \ll 1\) to provide the following condition for QNM frequencies:

\[
e^{-\pi \delta - 2i\delta \ln(m) - i\delta \ln(8\epsilon)} \frac{\Gamma^2(2i\delta)\Gamma(1/2 + s - im - i\delta)}{\Gamma^2(-2i\delta)\Gamma(1/2 + s - im + i\delta)} \times \frac{\Gamma(1/2 - s - im - i\delta)\Gamma(1/2 + i(m - \delta - \sqrt{2}\omega))}{\Gamma(1/2 - s + im + i\delta)\Gamma(1/2 + i(m + \delta - \sqrt{2}\omega))} = 1.
\]

(1)

Here we denote the eigenvalues of the angular Teukolsky equation by \(s_{l,m}^\pm\), and we define \(\delta^2 \equiv 7m^2/4 - (s + 1/2)^2\) and \(\omega \equiv (\omega - m\Omega_H)/\sqrt{\epsilon}\) [note that \(\Omega_H = a/(r_H^2 + a^2)\) is the horizon frequency and \(r_+ = 1 + \sqrt{1 - a^2}\) is the horizon radius]. Scalar, electromagnetic, and gravitational perturbations correspond to spin \(s = 0, -1, -2\), respectively. If we choose the conventions that \(Re(\delta) \geq 0\) and \(Im(\delta) \geq 0\) when \(\delta^2\) is positive and negative, respectively, then the left-hand side of Eq. (1) is usually a very small number, except when it is near the poles of the \(\Gamma\) functions in the numerator. When \(m \geq 0\), we can always find the solution near the poles at negative integers:

\[1/2 + i(m - \delta - \sqrt{2}\omega) = -n,\]

or

\[\omega = \frac{m}{2} - \frac{\delta}{\sqrt{2}} - i\left(n + \frac{1}{2}\right)\sqrt{\frac{\epsilon}{2}}.\]

Note that the overtone index \(n\) of these ZDM frequencies need not correspond precisely to the same overtone index of Kerr QNMs at lower spins. This set of solutions was first discovered by Hod [13]. The matched-expansion derivation shows that this set of modes depends on the near-horizon region of the Kerr BH. Equation (3) is quite accurate when \(\mid \delta \mid \gg 1\), but when \(\mid \delta \mid < 1\) it needs an additional correction [19]. However, the \(\sqrt{\epsilon}\) scaling of the decay rate is still correct when \(\mid \delta \mid < 1\). The solutions to Eq. (3) with \(m < 0\) are those that arise from the symmetry \(\omega_{l,m} = -\omega_{l,-m}\); there are no solutions with \(m < 0\) and \(Re(\omega) > 0\), when \(\omega - m/2\) is not small. Thus, the ZDMs only exist in the corotating regime \(m \geq 0\).

Another set of solutions of Eq. (1) may exist when \(\delta^2 < 0\) and \(2i\delta = -n\), with \(n\) a positive integer. A more detailed analysis shows that, in this case, two nearly degenerate hypergeometric functions have a comparable contribution to the near-horizon solution [19]. As a result, Eq. (1) is no longer valid when \(2i\delta = -n\). As a consistency check, we looked for solutions with \(2i\delta = -n\) using Leaver’s method and we did not find any.

III. WKB ANALYSIS

The matched-expansion method assumes that \(\omega = m/2\), but Eq. (1) does not hold for modes which do not meet this requirement (i.e., DMs). To compute these modes, we will instead use a WKB analysis in the eikonal limit \(l \gg 1\). The radial Teukolsky equation when \(l \gg 1\) is [15]...
with

\[ K = -\omega (r^2 + a^2) + am, \quad \frac{d}{dr} \frac{\Delta}{r^2 + a^2} = \frac{d}{dr}. \]

\[ \Lambda_{lm}^0 = A_{lm} + a^2 \omega^2 - 2am\omega, \quad \Delta = r^2 - 2r + a^2. \]

We define \( \omega = \omega_R - i\omega_I \), and we note that the real and imaginary parts scale as \( \omega_R \propto l \) and \( \omega_I \propto l^0 \), while the angular constant scales as \( A_{lm} \propto l^2 \). We only keep the leading-order terms in the eikonal limit in the following discussion (therefore all \( s \)-dependent terms are neglected, and the \( A_{lm} \) are real). In Fig. 2 and below, we will refer to \(-V_r\) as “the potential.” According to the WKB analysis and its geometric correspondence in Ref. [15], the position of the peak of the potential asymptotes the horizon as \( a \to 1 \) for some of the corotating modes. For this set of QNMs, one can verify that \( V_r^\eta \) (where primes denote derivatives with respect to \( r_s \)) scales as \( \Lambda^2 \); thus, the peak \( r_0 \) of the potential becomes broad as \( r_0 \) approaches the horizon. It then follows that \( \omega_I \propto \sqrt{F_0}/\partial_\omega V_r \to 0 \), and \( \omega_R \to m/2 \) in order to satisfy \( V_r(\omega_R, r_0) = 0 \) for these modes. Assuming that \( r_0 = 1 + c\sqrt{\epsilon} \) for the nearly extremal modes, where \( c \) is some constant, we can apply the eikonal equations in Ref. [15] and obtain

\[ V_r = L^2 \frac{(r - 1)^2}{(r^2 + 1)^2} \left[ \frac{(r + 1)^2}{4} - \mu^2 - \alpha (\mu) + \frac{3}{4} \mu^2 \right], \]

where \( L = l + 1/2 \) and \( \alpha (\mu) = A_{lm}/L^2 \). According to the WKB analysis of the radial Teukolsky equation [20], the QNM frequencies are determined by the peak of the potential. As shown in Fig. 2, when \( \mu \) is large the maximum of the potential is at the horizon, \( r = 1 \), as expected for ZDMs. As \( \mu \) decreases and falls below some critical value \( \mu_c \), the peak moves outside the horizon, and the horizon becomes a local minimum of the potential. At the peak \( \omega_I \) is non-zero because \( d^2 V_r/dr_s^2|_{r_0} \neq 0 \), so we have DMs. The criterion for having no peak outside the horizon is

\[ \frac{(r + 1)^2}{4} - \mu^2 - \alpha (\mu) + \frac{3}{4} \mu^2 > 0 \quad \text{for} \quad r = 1, \]

i.e., \( F_0^2 > 0 \) (or \( \delta^2 > 0 \)). The values at which \( F_0^2 \) (or \( \delta^2 \)) vanish lead to the condition for the critical \( \mu_c \): \( \alpha (\mu_c) = \frac{3}{4} \mu_c^2 \). If we use the approximation \( \alpha (\mu) = 1 - a^2 \omega^2 \) \( (1 - \mu_c^2) / (2L^2) \) [15], this will reproduce Hod’s approximate analytical result \( \mu_c \approx \left[ (15 - \sqrt{193}) / 2 \right] / 2 \) [16]. We can obtain the exact \( \mu_c \) (in the eikonal limit) by inserting \( \alpha (\mu_c) = \frac{3}{4} \mu_c^2 \) into the Bohr-Sommerfeld condition for \( \alpha \) derived in [15]:

\[ \int_{\theta_+}^{\theta_-} \sqrt{\alpha - \frac{\mu^2}{\sin^2 \theta} + \frac{\mu^2}{4} \cos^2 \theta} = \left( 1 - |\mu| \right) \pi, \]

where \( \theta_+ = \pi - \theta_+ \) and \( \theta_+ = \arcsin (\sqrt{3} - 1) \) are the angles at which the integrand vanishes. Therefore we have

\[ \mu_c = \frac{1}{1 + I/\pi}, \quad I = \int_{\theta_+}^{\theta_-} d\theta \sqrt{\frac{7}{4} - \frac{1}{\sin^2 \theta} + \frac{1}{4} \cos^2 \theta}, \]

which yields the numerical value \( \mu_c \approx 0.74398 \). In the eikonal limit, when \( \mu > \mu_c \), NEK BHs have only ZDMs (“single-phase regime”); when \( 0 \leq \mu \leq \mu_c \), both DMs and ZDMs exist (“double-phase regime”).

### IV. Phase Boundary

Although there is a clear criterion for determining the boundary between the single-phase regime and the double-phase regime in the eikonal limit (when \( \mu < \mu_c \), the peak of the potential no longer resides on the horizon), it is not immediately clear if a similar criterion holds when \( l \) is small. For scalar perturbations, however, we can write the radial Teukolsky potential for extreme-Kerr BHs with generic \( l, m \), under the assumption that \( \omega = m/2 \) (and, therefore, the \( \omega_{lm} \) remain real for the ZDMs):

\[ V_r = \left( r - 1 \right)^2 \left[ \frac{(r + 1)^2}{4} m^2 - \omega_{lm} \right] - \frac{(r - 1)^2}{4} \frac{2m^2 + (r - 1)(2r^2 + 3r - 1)}{(1 + r^2)^2} \]

It is not difficult to see that there is still no peak outside the horizon when \( \frac{3}{4} m^2 > \omega_{lm} \), or \( F_0^2 > 0 \). For electromagnetic and gravitational perturbations the potential terms \( -V_r \) are complex functions, thereby making the positions of their extrema more difficult to define. Detweiler [21], however, has shown that the radial function can be transformed so that it satisfies a differential equation with a real potential. Using this potential, the criterion to exclude peaks outside the horizon is [19]

\[ F_0^2 = \frac{7}{4} m^2 - s(s + 1) - \omega_{lm} \left( \omega = \frac{m}{2} \right) > 0. \]

Note that this expression respects the pairing symmetry \( -\omega_{lm} = \omega_{lm} + 2s \), and that for all \( s \), \( F_0^2 \) and \( \delta^2 \) differ.
from each other only by 1/4. For \( s = 0, -2 \) and \( 2 \leq l \leq 100 \), we have searched all QNMs numerically and have not found any mode simultaneously satisfying \( \delta^2 < 0 \) and \( \mathcal{F}_l^2 > 0 \); therefore, the sign of \( \delta^2 \) also determines whether a peak exists outside the horizon. In addition, we have used Leaver’s continued-fraction algorithm to determine the phase boundary numerically. As shown in Fig. 1, the actual phase boundary matches the criterion predicted by the eikonal limit, \( \mu = \mu_c \). In addition, for scalar and gravitational perturbations, we find numerically that modes are in the single-phase regime when \( \mathcal{F}_l^2 > 0 \) for all \( l \leq 15 \). This reinforces our physical understanding that DMs are associated with a peak of the potential outside the horizon, while ZDMs are somewhat similar in nature to the \( s \) modes in ultracompact stars [18].

V. BIFURCATION

Schwarzschild and slowly spinning Kerr BHs have a single set of QNMs for each \( l, m \) that are characterized by their overtone number \( n \). If the ZDMs originate from modes at higher \( n \) than the DMs when the BH spin is low, then when the spin increases beyond a critical value \( a_s = 1 - \epsilon_s \), a single set of QNMs may split into two branches.

We numerically investigate this bifurcation effect by examining the complex QNM frequency plane to search for solutions of Leaver’s continued-fraction equations [17,19]. In Fig. 3, we plot the contours of constant value of the logarithm of the continued-fraction expansion, truncating at \( N = 800 \) terms. The QNM frequencies correspond to the local minima of this sum, where the

![Image of contour plots]

FIG. 3 (color online). QNM frequencies with \( l = 10 \) for NEK BHs. Contours are constant values of the logarithm of the continued fraction in the complex plane; darker shading indicates values near zero. The + symbols are the ZDM predictions, a \( \times \) is the lowest-overtone WKB prediction from [15], and the box is centered at the WKB prediction from Eq. (5). No branching is observed for modes with \( m = 8 \). Note that the closed contours with light shading have large values and do not correspond to any QNM. Further discussion of the figure is in the text.
contours cluster. The shading indicates the value of the fraction, with darker values nearly zero.

When \( \mu < \mu_c \), a single set of QNMs splits into two branches for increasing \( a \) (see the left-hand panels of Fig. 3, where \( l = 10, m = 7 \), as the spin increases from \( a = 0.9990 \) to \( a = 0.9999 \) from the upper panel to the lower). The ZDM branch is quite accurately described by Eq. (3); the imaginary part of the ZDMs scales like \( \sqrt{\epsilon} \), and they move towards the real axis as \( \epsilon \to 0 \). The DM branch changes relatively little with increasing spin (it is expected that the WKB peak can only support a finite number of modes \cite{19}, and there are only three DMs in the lower-left panel). In this case, the WKB formulas of Ref. [15] are in good agreement with the lowest-overtone ZDM in the high-overtone limit \cite{22}, where these predictions are accurate for these high-overtone DMs, finding an analytic solution for \( a_c \) remains an open problem.

For \( \mu > \mu_c \) there is no bifurcation, and the modes are predicted fairly well by Eq. (3). We can see this in the right-hand panels of Fig. 3, where \( l = 10, m = 8 \), and we again raise the spin from \( a = 0.9990 \) to \( a = 0.9999 \). For the \( m = 8 \) modes, we also mark the leading-order WKB prediction of Eq. (5) with a box. For the bifurcation effect, we can define a benchmark \( a_c = 1 - \epsilon_c \) as the BH spin at which the imaginary part of the fundamental ZDM is equal to that of the fundamental DM:

\[
\frac{\sqrt{\epsilon}}{\sqrt{2}}(1 + 2|\delta|) = \frac{1}{2} \frac{\sqrt{2\beta^*}}{\partial_{\alpha}\beta} \bigg|_{r_0}.
\]

The right-hand side of Eq. (12) can be evaluated using the approximate WKB formula in Ref. [15]. Since both sides of Eq. (12) depend on \( \epsilon \), we solve for \( \epsilon_c \) iteratively; this converges quickly for a variety of initial spins. By computing \( \epsilon_c \) for \( l = 15 \) and \( 0 < m < (l + 1/2)\mu_c \), we find that \( L^2 \epsilon_c = 10^{-3} (11.6 - 3.12\mu_c - 18.0\mu_c^2) \) is a reasonable fitting formula. For the \( l = 10, m = 7 \) case, Eq. (12) gives \( \epsilon_c \sim 10^{-5} \), which is in agreement with numerical results; for the \( l = 2, m = 1 \) case it gives \( \epsilon_c \sim 10^{-3} \).

In Fig. 3, however, it is clear that the bifurcation actually starts when the fundamental ZDM’s imaginary part equals the imaginary part of the highest-overtone DM (in Fig. 3 it is the third overtone). This happens at a spin \( a_c < a_c \). Because we do not have a good estimate of the number of modes in the DM branch (beyond the fact that it should be proportional to \( L \) and a function of \( \mu \) in the eikonal limit \cite{19}) and because WKB techniques are not accurate for these high-overtone DMs, finding an analytic solution for \( a_c \) remains an open problem.

VI. CONCLUSIONS

We identified two different regimes in the NEK QNM spectrum. In the double-phase regime, we found that the lowest ZDM becomes less damped than the lowest DM at some critical \( a_c \), for which we provided an analytical estimate. For sufficiently large \( a \), Eq. (3) is accurate at the least for those ZDMs with smaller decays than the point where the branches bifurcate. We estimate that the number of ZDMs below the bifurcation is \( \sim \sqrt{\epsilon}/\epsilon \) \cite{19}. In the future, we would like to investigate the behavior of the ZDM branch in the high-overtone limit \cite{22}, where these approximations break down.
