Rhinoology

Predictive role of nasal functionality tests in the evaluation of patients before nocturnal polysomnographic recording

Ruolo predittivo dei test di funzionalità nasale in pazienti da sottoporre a polisonnografia

Summary

Obstructive sleep apnoea syndrome is a disease characterized by a collapse of the pharyngeal airway resulting in repeated episodes of airflow cessation, oxygen desaturation, and sleep disruption. It is a common disorder affecting at least 2-4% of the adult population. The role of nasal resistance in the pathogenesis of sleep disordered breathing and sleep apnoea has not been completely clarified. Aim of the present study was to establish whether nasal resistance and nasal volumes, measured by means of Active Anterior Rhinomanometry and Acoustic Rhinometry together with Mucociliary Transport time play a positive predictive role in the evaluation of Obstructive sleep apnoea syndrome patients before running a nocturnal polysomnographic recording. A retrospective study was performed analysing 223 patients referred for suspected Obstructive sleep apnoea syndrome. All patients were submitted to complete otorhinolaryngological evaluation and underwent nocturnal polysomnography. On the basis of polysomnographic data analysis, the apnoea-hypopnoea index and snoring index, patients were classified into two groups: Group 1 (110/223 patients) with a diagnosis of mild-moderate Obstructive sleep apnoea syndrome (apnoea-hypopnoea index < 30) and Group 2 (113/223 patients) affected by snoring without associated hypoxaemia/hypercapnia. A control group of 76 subjects, not complaining of sleep disorders and free from nasal symptoms was also selected. The results showed, in all the snoring and Obstructive sleep apnoea syndrome patients, total nasal resistance and increased Mucociliary Transport time compared to standard values. Furthermore, the apnoea-hypopnoea index was significantly higher in patients with higher nasal resistance and significantly different between the groups. These results allow us to propose the simultaneous evaluation of nasal functions by Active Anterior Rhinomanometry, Acoustic Rhinometry, and Mucociliary Transport time in the selection of patients undergoing polysomnography.

Key words: Sleep respiratory disorders • Obstructive sleep apnoea syndrome • Nasal functionality tests • Polysomnography

Riassunto

La sindrome delle apnee ostruttive del sonno, patologia che affligge circa il 2-4% degli adulti, è una malattia caratterizzata dal collasso delle strutture faringee con conseguenti ripetuti episodi di desaturazione, pause respiratorie e risvegli notturni. Ipotizzando che lo studio della funzionalità nasale possa avere un ruolo predittivo in questi pazienti prima di effettuare un esame polisonnografico abbiamo retrospettivamente analizzato le cartelle di 223 pazienti afferenti all’ambulatorio di Rinologia che riferivano disturbi del sonno. Tutti i pazienti erano stati sottoposti a completa valutazione obbiettiva otorinolaringoiatrica, studio della funzionalità nasale mediante rinomanometria, rinometria acustica, valutazione del tempo di trasporto mucociliare e polisonnografia. I pazienti sono stati suddivisi in due gruppi in base ai valori di polisonnografia (Apnoea-Hypopnoea Index AHI/ Snoring index SI): Gruppo 1 (110/223 pazienti) affetti da OSAS (AHI < 30) lieve e moderata; Gruppo 2 (113/223 pazienti) con diagnosi di rassamento semplice senza segni di ipossiemia ed ipercapnia. I risultati hanno evidenziato nei pazienti affetti da rassamento semplice e OSAS, valori di resistenze nasali e di tempo di trasporto mucociliare più elevati rispetto al gruppo di controllo. All’analisi statistica lo AHI era significativamente elevato nei pazienti con elevate resistenze nasali totali. Alla luce dei nostri risultati riteniamo utile la simultanea valutazione della funzionalità nasale mediante rinomanometria, rinometria acustica e valutazione del tempo di trasporto mucociliare per indirizzare i pazienti verso un esame polisonnografico.

Parole chiave: Disturbi respiratori del sonno • Sindrome delle apnee ostruttive nel sonno • Prove di funzionalità nasale • Polisonnografia
Obstructive sleep apnoea syndrome (OSAS) is a pathological condition characterized by a collapse of the pharyngeal airway resulting in repeated episodes of airflow cessation, oxygen desaturation, and sleep disruption. It is a common disorder affecting at least 2-4% of the adult population and it is increasingly recognized by the public. Clinically, OSAS is defined by the occurrence of daytime sleepiness, loud snoring, witnessed breathing interruptions, or awakenings due to gasping or choking in the presence of at least 5 obstructive respiratory events (apnoeas, hypopnoeas or respiratory effort-related arousals) per hour of sleep. The presence of 15 or more obstructive respiratory events per hour of sleep, in the absence of sleep-related symptoms, is also sufficient for the diagnosis of OSAS due to the greater association of this severity of obstruction with important consequences such as increased cardiovascular disease risk.

The relationship between obstructed nasal passages and sleep-disordered breathing has been studied for over 30 years. It has been speculated that increased nasal resistance (NR) may be associated with increases in snoring activity and apnoic events during sleep. Some studies have demonstrated a weak association between NR and the severity of obstructive sleep apnoea. On the contrary, others did not show any correlation between the degree of nasal obstruction and the severity of snoring or sleep apnoea.

In the present study, by focusing on nasal functions, measured by Active Anterior rhinomanometry (AAr), Acoustic rhinometry (Ar) and the evaluation of nasal muco-Ciliary Transport time (mCTt), a group of patients was examined suffering from OSAS and a group of patients suffering from Primary Snoring (PS) i.e., snoring without associated hypoxaemia, hypercapnia, sleep disruption or daytime symptoms and these data were then compared with those in a control group without sleep disorders. The aim was to establish whether the status of the nasal passages has a significant predictive role in the evaluation of these patients before running a nocturnal polysomnographic recording.

Materials and methods

Patients
Inclusion criteria were age > 18 years, body mass index (BMI) < 33, tonsil size Grades 1 and 2, elongated uvula, all Mallampati grades, minimal collapse of the tongue base (< 25%) as seen on the modified Müller manoeuvre, Fujita (retro-palatal obstruction) Grade 1, simple snorers (apnoea-hypopnoea index AHI < 5), and patients with mild-moderate OSA (AHI < 30). All patients had had a previous complete ENT evaluation, including clinical examination, fiberoptic nasopharyngoscopy with modified Müller manoeuvre; then all underwent nasal functionality tests and more precisely: AAR, AR and nasal MCTt determination. Nocturnal polysomnography was, thereafter, performed on all the patients.

Fiberoptic nasopharyngoscopy
The clinical evaluation included a complete traditional ENT examination of the upper airways and an endoscopic examination, with a flexible fibroscope (Olympus LF-DP, Tokyo, Japan), of the nasal, nasopharyngeal, and hypopharyngeal cavities. During this latter examination, a modified Müller manoeuvre was performed in the oropharyngeal areas (retropalatal region). Otorhinolaryngologic findings of the upper airway were graded as follows:

1) Tonsil size
Grade 1: tonsils are in tonsillar fossa, barely seen behind the anterior pillars.
Grade 2: tonsils are visible behind the anterior pillars.
Grade 3: tonsils are extended three quarters of the way to the mid-line.
Grade 4: tonsils are completely obstructing the airway.

2) Modified Mallampati grade (MMP)
Grade 1: tonsils, pillars and soft palate are clearly visible.
Grade 2: uvula, pillars and upper pole are visible.
Grade 3: soft palate is partly visible; while tonsils, pillars and the uvula base are all invisible.
Grade 4: hard palate only is visible.

3) Fujita scale
Type 1: collapse of palato-pharyngeal arch only.
Type 2: collapse of palato-pharyngeal arch and retroglossal space.
Type 3: collapse of retroglossal space only.

4) Retroglossal space
Grade 1: the retroglossal space is widely patent allowing visualization of the oropharynx.
Grade 2: the retroglossal space hardly allows visualization of the oropharynx but the opposite walls are not in contact.
Grade 3: the retroglossal space is very narrow with the barely contacting opposite walls.
Grade 4: the retroglossal space is in constant contact with the opposite walls.

Sleep Study
Standard overnight polysomnography (Alice 3, Healthdyne, Technologies, Ohio, USA) was performed in a conventional manner to record sleep parameters and architecture in every patient. The electro-encephalogram (EEG), electrooculogram (EOG), electromyogram (EMG) and electrocardiogram (ECG) were recorded continuously, and respiration was monitored with oro-nasal thermistors and
Thoraco-abdominal piezo sensors. The parameters used in this study were AHI, snoring index (SI) and minimal oxygen saturation (MSAT). AHI was defined as the total number of apnea and hypopnea episodes per hour of sleep. An apnea episode was defined as cessation of airflow lasting longer than 10 seconds, whereas a hypopnea episode was defined as a reduction of 50% or greater in combined oral and nasal flow lasting longer than 10 seconds. SI was defined as the number of spikes in sound intensity exceeding 50 dB per hour of sleep. MSAT was defined as the minimal O2 saturation detected during the polysomnographic test period. The single technician who scored the polysomnographic studies was blind to NR measurements.

Nasal Airflow study

Rhinomanometry

Nasal resistance was measured by AAR (Ryno Zig Rhinomanometer by Menfis Biomedica srl, BO, Italy) in the daytime. Active rhinomanometry is a quick test that requires subjects to generate airflow through the nose by their own effort. In accordance with the International Committee on standardization of rhinomanometry, the nasal airflow resistance was measured at standard pressure (150 Pa), and the total nasal resistance was calculated from the unilateral rhinomanometry recordings. The measurements were not taken during the symptomatic period for acute common cold or seasonal allergic rhinitis, and patients in whom nasal resistance was not measurable due to severe nasal obstruction were excluded from this study. In contrast to other studies, we measured total nasal resistance only in the sitting position which allowed us to determine a stable situation of the upper airways (not influenced by wakefulness/sleep or sitting/supine position) and its eventual influence on snoring or sleep apnoea.

Acoustic rhinometry

Acoustic rhinometry (Rhinoklack-RK1000, Stimotron Co., Wendelstein, Germany) was performed while the patient was breathing quietly after inserting a nocepiece into the nostril. This technique evaluates nasal patency by analysing reflections of a sound pulse introduced by the nostril. By analysing the amplitude of sound reflected from the nasal cavity, an estimate of cavity geometry can be produced by PC-software as a plot of the cross sectional area against the distance from the nostril. In this graph, narrowing is seen as a peak and widening as a dip. Minimal nasal cross-sectional areas, cross-sectional areas, at a defined distance from the nostril and volumes of defined regions of nasal cavities, can be derived by further manipulation of the data. We added these values to our analysis because, on the basis of our previous studies, acoustic rhinometry is more specific and more sensitive than rhinomanometry in diagnosing rhinopathies in patients with structural anomalies.

In this research, it was found that symptom scores, as rated by patients on a visual analogue scale frequently did not correlate with objective measurements, as patients often overestimated the severity of their obstruction. On the contrary, for a few patients, a correlation between symptom scores and MCTt could be observed. This is why we performed also this test in all our patients.

Evaluation of Nasal Muco-Ciliary Transport time

All subjects underwent nasal MCTt determination using a mixture of charcoal powder and 3% saccharin. Nasal MCTt is calculated as being the time elapsing between the moment in which the charcoal powder is placed on the head of the inferior turbinate and the moment in which a blackish colouring appears in the oro-pharynx, as shown by direct pharyngoscopy; saccharin clearance, on the other hand, is calculated at the moment in which the subject being tested notices a sensation of sweetness.

Statistical analysis

All statistical analyses were made using the SPSS for Windows. Continuous variables (age, height, body weight, BMI) were compared with the independent t test. The clinical data and PSG variables are expressed as mean values ± SD. The correlation between nasal resistance and the parameters monitored during PSG were evaluated using the Mann-Whitney test.

Assuming nasal resistance as a reference value for the severity of OSAS, the specificity, sensitivity, and positive and negative predictive values of nasal function test were calculated using the standard technique to obtain the Receiver Operator Characteristics (ROC) curve. A p value < 0.05 was considered statistically significant.

Results

This retrospective study was performed analyzing 223 patients (77 female, 145 male; age range 25 to 77 years, mean age 53 ± 14 SD) referred to the E.N.T. Clinic of Siena for suspected OSAS, from January 2002 to December 2005. On the basis of polysomnographic data (AHI and SI), patients were divided into two groups as follows: Group 1 (110/223 patients) with a diagnosis of mild-moderate OSAS (AHI < 30) and Group 2 (113/223 patients) affected by snoring without associated hypoxae mia, hyper-capnia, sleep disruption or daytime symptoms (AHI < 5). These two patient groups were compared with a control group (Group 3), comprising 76 adults (27 female, 49 male, age range 27 - 75 years, mean age 57 ± 16 SD) free from nasal symptoms or upper respiratory infections for at least 2 weeks, and without sleep or snoring complaints.
no significant correlation between nasal resistance and
other anthropometric parameters (patient age, height,
body weight, BMI) was observed (P > 0.05).
The results of AAr, Ar and mCTt in the mild-moderate
OSAS group, in snoring group and in a control group are
shown in Table I.
Total nasal resistance correlated significantly, and
in the expected direction, with Ahi (p = 0.006) (Fig.
1). The values of nasal mCTt were also significantly
 correlated with Ahi (p = 0.004) (Fig. 2). There was
no significant correlation between rhinomanometric
parameters and polysomnography. As far as concerns
the rhinometric parameters, a decrease of the minimal
cross-sectional areas was observed in all the patients,
but no statistically significant correlation with AHI was
observed.
Total NR also correlated with SI (p = 0.02): inter-group
comparison revealed a significant difference in SI with the
higher NR group showing higher SI.

Table I. Study population data.

| Study Groups | Control Group |
|--------------|---------------|
| | Mean ± SD |
| No. | 223 (110 Group 1) (113 Group 2) 76 |
| Age (yrs) | 53 ± 14 57 ± 16 |
| Body Mass Index | 31.3 ± 0.7 (Group 1) 27.4 ± 0.5 (Group 2) 20.4 ± 0.3 |
| AHI | 25.3 ± 2.7 (Group 1) 4.78 ± 0.5 (Group 2) < 1 |

AHI: apnoea-hypopnoea index

Table II. Results of nasal functionality tests in the three groups of patients.

| | Group 1 | Group 2 | Group 3 |
|--------------|---------|---------|---------|
| AAR | 0.25 ± 0.03 Pa/cc3/sec | 0.33 ± 0.02 Pa/cc3/sec | 0.40 ± 0.06 Pa/cc3/sec |
| AR | 1.1 Cm2 | 0.83 Cm2 | 0.66 Cm2 |
| MCTt | 13 +/- 2 Min. | 16.9 +/- 2 Min. | 17.55 +/- 2 Min. |

Fig. 1. Nasal resistance value.
AAR: Active Anterior Rhinomanometry

Fig. 2. Muco-Ciliary Transport time (MCTt).

Fig. 3. ROC curve of nasal resistance in detecting patients with mild-moderate OSAS.
Stepwise multiple regression models revealed that high NR was predictive of AHI (p = 0.006).
The ROC curve of nasal resistance is shown in Figure 3, without a specific cut-off point; the possibility to identify patients with mild-moderate OSAS is greatly affected by varying the threshold value along the curve.

Discussion
OSAS affects, at least, 2-4% of the adult population and is increasingly recognized by the public. The pathophysiology of OSAS involves the development of pharyngeal airway narrowing. The pharyngeal airway may behave like a Starling resistor due to decreased upper airway muscle tone and phasic inspiratory activity during sleep. The collapsibility of the compliant wall is further enhanced by the increased resistive load caused by obesity which alters the physical characteristics of the wall.

The pharynx, connecting the nose to the larynx and acting as a Starling resistor, is more vulnerable to changes in airflow resistance. On the other hand, the nose has a rigid framework to maintain constant resistance both in waking and sleeping states. Thus, the role of NR in OSAS remains controversial.

A large number of adult surveys have been conducted in order to establish the presence or absence of OSAS by means of parameters such as age, sex, snoring, witnessed apnoea and daytime sleepiness, and giving a score for each clinical feature suggestive of sleep apnoea.

Our results showed that in snoring and mild-moderate OSAS patients the values of nasal resistance and MCTt are increased with respect to standard values whereas minimal cross-sectional areas are decreased. Specifically, a nasal resistance of 0.40 ± 0.06 Pa/cc3/sec, a minimal cross sectional area of 0.66 cm² and a MCTt of 17.55 min could be predictors of AHI and SI (Table II).

In this study, SI was significantly higher in patients with higher NR and significantly different in the three groups (p = 0.02).
