ABSTRACT

In this Letter, we briefly describe the evolution of a variety of self-gravitating protoplanetary disk models that contain annular grooves (e.g., gaps) in their surface density. These grooves are inspired by the density gaps that are presumed to open in response to the formation of a giant planet. Our work provides an extension of the previously studied groove modes that are known in the context of stellar disks. The emergence of spiral gravitational instabilities is predicted via a generalized eigenvalue code that performs a linear analysis and confirmed with hydrodynamical simulations. We find that the presence of a groove drives a fast-growing two-armed mode in moderately massive disks and extends the importance of self-gravitating instabilities down to lower disk masses than for which they would otherwise occur. We discuss the potential importance of the instability in the context of planet formation, e.g., the modification of the torques driving type II migration.

Subject headings: hydrodynamics — planetary systems

1. INTRODUCTION

The theory of giant planet formation has evolved very rapidly over the past decade, and the now near-paradigmatic core accretion theory (e.g., Pollack et al. 1996) has been greatly refined and endowed with a variety of physical inputs (see, e.g., Alibert et al. 2004; Hubickyj et al. 2005). It is now generally accepted that Jupiter-mass planets grow by initially accumulating 5–10 $M_{\oplus}$ cores, which then accrete large quantities of gas from the surrounding nebula. During the rapid gas accretion phase, the growing Jovian planet opens a gap in the disk and its orbit subsequently evolves via the process of type II migration (Lin et al. 1996; Papaloizou et al. 2007).

A competing theory (e.g., Boss 2000) holds that giant planets such as Jupiter fragmented directly from the nebula as a result of gravitational instabilities (GIs). This mechanism may account for some of the observed extrasolar planets, but it has a number of difficulties if invoked to account for the full population. In particular, it fails to explain the observationally well-established planet-metallicity relation (Santos et al. 2003; Fischer & Valenti 2005). Another criticism is that GI requires the Toomre $Q$ parameter, $Q = \kappa c_{s} / \pi G \sigma$, to be of order unity at some radius in the disk. This, however, generally requires rather massive disks, $M_{\text{g}}/M_{\text{sur}} \approx 0.1$, which are not often observed.

Global GIs depend not just on disk mass and sound speed but also on the density profile of the disk. As shown by Toomre (1981), a sharp density gradient (i.e., “edges”) can drive a wave cycle that leads to the subsequent destruction of the edge. Analogously, Sellwood & Lin (1989, hereafter SL89) described a family of GIs in stellar disks dubbed groove modes that comprise fast-growing disturbances driven by narrowly defined structures in particle angle-action space. These features, in physical space, correspond to narrow density depressions; groove modes are thus akin to the edge mode in that they are driven by steep density gradients at corotation. SL89 further envisioned a feedback cycle that kicks in when a slowly growing intrinsic mode (i.e., an inner edge mode) carves a groove by scattering particles in a narrow range at its Lindblad resonance and creating a fast-growing groove mode; the new groove gives rise to further groove modes once it travels to its own Lindblad resonances.

This feedback cycle relies on the wave-particle interaction at the resonances and thus cannot be immediately realized in a gaseous disk. The groove mode may have relevance, however, in the protoplanetary context: theoretical considerations (Lin & Papaloizou 1979; Goldreich & Tremaine 1980; Lin & Papaloizou 1993), numerical simulations (e.g., Takeuchi et al. 1996; Bryden et al. 1999), and tentative observational indications (Setiawan et al. 2008) point to the fact that massive planets can resonantly drive trailing waves that transport angular momentum and open a “gap” in the disk. The detailed process of opening and maintaining the gap depends on the balance between the angular momentum flux resulting from spiral waves driven by the planet and that due to the viscosity of the disk. When the planet is sufficiently massive and the viscosity is low enough, a stable groove can be naturally carved and maintained on the disk.

In this Letter, we open an investigation into the possibility that the planet-induced density gap can drive a fast-growing, self-gravity-induced groove mode in a disk, sidestepping the problems of carving a groove in the first place and providing a mechanism for maintaining the amplifier. We support our hypothesis with both a linear mode analysis (see, e.g., Adams et al. 1989) and a full hydrodynamical simulation (following Laughlin & Rozyczka 1996, hereafter LR96) of a disk with an imposed groove in surface density, as inspired by previous numerical investigations for stellar disks (e.g., Sellwood & Kahn 1991). We span a range of mass ratios to assess the relevance of this GI to the realistic disk masses observed.

2. PROCEDURE

We employ a two-dimensional hydrodynamical grid code for following the evolution of a thin, self-gravitating disk. The continuity and Euler equations in polar coordinates are solved using a second-order van Leer–type scheme, coupled with time stepping that is first-order accurate. The basic difference equations are given in Stone & Norman (1992). The self-gravity of the disk is obtained by applying the Fourier convolution theorem to the potential dictated by the Poisson equation (Binney & Tremaine 1987). The details of the hydrodynamical code are described in Laughlin et al. (1997) and related papers.
We adopt the following parametrization for the surface density of the disk:

\[
s(\theta) = \sigma_0 e^{i-(r-R_g)^2/\Delta^2} \times \left[ 1 - \frac{A\Delta^2}{(r-R_g)^2 + \Delta^2} \right],
\]

which represents a Gaussian profile multiplied by a Lorentzian gap of depth \( A \), semiaxis width \( \Delta \), and central position \( R_g \); for \( A = 0 \), this profile is the “reference disk” considered by LR96. The disk model used throughout this Letter has no pretense of actually representing a protoplanetary disk faithfully but has the advantage of possessing a single intrinsic \( m = 2 \) mode for \( A = 0 \) that is clearly identifiable both in semianalytic calculations and in the nonlinear simulations. The choice of a Lorentzian profile to represent the gap is arbitrary as well and follows Sellwood & Kahn (1991). We take \( r_w = 0.03, R_g = 0.25 \), and an inner edge of 0.05. A polytropic equation of state is assumed, \( P = \mathcal{K} \rho^\gamma \) with \( \gamma = 2 \) (again, this is chosen largely for illustrative purposes). The characteristic width \( \Delta \) is meant to represent a typical gap width; the chosen value of 0.07 can be derived from the approximate scaling derived by, e.g., Varnière et al. (2004) with \( R \sim 5 \times 10^5 \) and \( q = 2 \times 10^{-3} \). The set of units used in the code takes the outer grid radius \( R_g \) and the gravitational constant \( G \) equal to unity and \( M = 0.5 \).

To quantify the strength, pattern speed, and growth rate of each spiral mode, we compute the Fourier decomposition of the surface density, defined as

\[
a_m = \frac{1}{2\pi} \int_0^{2\pi} s(\theta, \Phi) e^{-im\theta} d\Phi = c_m \times a_0,
\]

for a mode number \( m \). A global measure of the growth of a particular mode is given by integrating the \( m \)th Fourier amplitude \( a_m \) over the radial range and normalizing to the azimuthal average of the surface density:

\[
C_m = \frac{\int_{R_{\text{in}}}^{R_{\text{out}}} a_m(r) dr}{\int_{R_{\text{in}}}^{R_{\text{out}}} \sigma(r) dr}, \quad \gamma_m = \frac{d}{dt} \log C_m.
\]

We refer the reader to the original paper for a detailed explanation of the calculations and results.
our purposes, the linear growth rate is the primary quantity of interest.

A second set of disk parameters (model 2) including a density groove was set up, with \( \Lambda = 0.90 \) (a 90% dip), \( \Delta = 0.07 \), and \( \mathcal{R}_p = 0.4 \). Maintaining the same normalizations for density and pressure as above, the disk has the same density profile sufficiently far from the groove but a smaller disk-to-star mass ratio, \( q_p = 0.63 \). By visual inspection of Figure 2 and the slope of the normalized Fourier amplitude in Figure 3, it is clear that the presence of the groove drives a far more violently growing instability. The dashed linear slope is derived from the mode analysis for the same disk parameters and agrees well with the hydrodynamical code; the small discrepancies between the two methods can be traced to the effective softening given by the FFT-based solution scheme for the Poisson equation. We then varied the density normalization to yield \( q_p = 0.32, 0.16, 0.13, 0.08, \) and 0.06 (models 3–11).

Measuring the pattern speed is more complex, since the spiral rotates only approximately in a rigid fashion. We thus calculate a “global” measure \( \Omega_p \) by weighing the local \( \Omega_p(r) \) with the local density enhancement \( |c_m| \), so that the densest parts of the spiral contribute the most to the pattern speed. The corotation radius of the models with a groove is found to lie within the gap, confirming its nature as a groove mode and in accordance with that found by Sellwood & Kahn (1991).

Since the presence of the groove diminishes the \( q_p \) parameter for a given density normalization, we also set up a series of base disks (models 12–17) with a density normalization chosen so that its mass would equal that of models 2–7. For a given \( q_p \), the presence of the groove the \( m = 2 \) mode exponentiates about 3–4 times faster than the base disk. Models 14–17, despite having equal disk mass and similar \( Q_{\text{min}} \) to their groovy counterparts, do not show an exponential phase during the duration of the simulation. A growing groove mode is detectable down to \( q_p = 0.06 \) (model 6) but does not show a resolvable exponential phase for \( q_p = 0.08 \) (model 7). The \( m = 2 \) groove instability in model 6 is growing about as fast as model 13, which is 4 times as massive.

The natural outcome for the unstable models is the transport of mass and angular momentum, resulting in the filling of the gap. An approximate estimate for the effective \( \alpha \)-type viscosity coefficient (Shakura & Syunyaev 1973) is derived by a procedure similar to that employed in LR96, although the effective viscosity given by GIs is not well characterized by a local prescription. We solved the diffusion-type equation for the time-dependent surface density and compared it with the evolution in the hydrodynamical simulation, once the spiral pattern has established itself. This simple estimation yields \( \alpha \sim 0.16 \) for \( q_p = 0.13 \) and \( \alpha \sim 0.04 \) for \( q_p = 0.08 \) and agrees approximately with the timescale for closing the gap via viscous diffusion.

4. DISCUSSION AND CONCLUSION

In this Letter, we have found that disk self-gravity may play a significant and as yet largely unstudied role in disks in which a planet has opened a gap in the surface density profile of the disk. Gravitational torques from massive protoplanets necessarily impart a surface density gap in a disk, and the formation of a gap provides the structure needed both for a feedback amplifier (e.g., Toomre 1981) and for the groove mode (SL89). In essence, a gap provides a pressure gradient that can locally reduce the effectiveness of the epicyclic frequency in stabilizing the disk against its own self-gravity, thus allowing instability at low surface densities. In the absence of a perturbing planet, the nonlinear outcome of a groove instability would be to destroy the sharp density gradient that promoted the instability in the first place. In a planet-forming disk, however, the embedded Jovian planet will exert torques whose net effect is to maintain the gap. The competition between the GI-induced torques and the planetary torques may thus lead to a significant modification of the criterion for gap opening (as evidenced by
the large effective viscosity found in our experiments), which
in turn can have a significant effect on the resulting migration
and growth of the protoplanet. We have found that this effect
is likely to be relevant even when the disk mass is lower than
the $q_D > 0.1 – 0.2$ value at which significant GIs are generally
thought to occur (see, e.g., Shu et al. 1990; Boss 1997; LR96).
By comparison, the typical mass within 30 AU assumed for
the minimum-mass solar nebula yields $q_D \approx 0.01$ (this is likely
an underestimate by a factor of 3). Further afield, Andrews &
Williams (2005) surveyed 153 young stellar objects in the Tau-
rus Aurigae star-forming complex and found a median disk
mass of $q_D = 0.005$. While these disks span a variety of ages
and show a variety of masses, it is not clear how massive the
average protoplanetary disk is at the time when cores enter the
rapid gas accretion phase and whether the mass might be
enough to trigger the instability studied here. It must also be
kept in mind that while the idealized disks in the simulations
shown here display no GI for $q_D < 0.08$, the limited numerical
resolution and high intrinsic numerical viscosity allow us to
identify only modes with intrinsically rapid growth rates. Fur-
ther work with realistic disk models is required to find the true
minimum mass for the instability. We are eager to continue
this analysis by (1) including the planetary potential both in
our linear analysis and in our nonlinear simulations, (2) car-
rrying out the simulations at higher numerical resolution, and
(3) adopting more realistic disk models.

We thank Dr. F. Adams and Dr. D. N. C. Lin for useful
discussions and our anonymous referee for the encouraging
and thorough critique. This research was supported by the NSF
through CAREER Grant AST-0449986 and by the NASA Or-
iginsof Solar Systems Program through grant NNG04GN30G.
