ABSTRACT

We report the discovery of two new transiting hot Jupiters, KOI-135b and KOI-204b, which were previously identified as planetary candidates by the Kepler team, and independently confirm the planetary nature of Kepler-17b, recently announced by Désert et al. (2011, ApJS, 197, 14). Radial-velocity measurements, taken with the SOPHIE spectrograph at the Observatoire de Haute-Provence (France), and Kepler photometry (Q1 and Q2 data) were used to derive the orbital, stellar, and planetary parameters. KOI-135b and KOI-204b orbit their parent stars in ~3.02 and 3.25 days, respectively. They have approximately the same radius, $R_p = 1.20 \pm 0.06$ $R_{\text{Jup}}$ and 1.24 ± 0.07 $R_{\text{Jup}}$, but different masses $M_p = 3.23 \pm 0.19 M_{\text{Jup}}$ and 1.02 ± 0.07 $M_{\text{Jup}}$. As a consequence, their bulk densities differ by a factor of four, $\rho_p = 2.33 \pm 0.36$ g cm$^{-3}$ (KOI-135b) and 0.65 ± 0.12 g cm$^{-3}$ (KOI-204b), meaning that their interior structures are different. All three planets orbit metal-rich stars with [Fe/H] ~ 0.3 dex. Our SOPHIE spectra of Kepler-17 were used both to measure the radial-velocity variations and to determine the stellar atmospheric parameters, allowing us to refine the characterisation of the planetary system. In particular we found the radial-velocity semi-amplitude and the stellar mass to be respectively slightly smaller and larger than in Désert et al. These two quantities, however, compensate and lead to a fully consistent planetary mass. Our analysis gives $M_p = 2.47 \pm 0.10$ $M_{\text{Jup}}$ and $R_p = 1.33 \pm 0.04$ $R_{\text{Jup}}$. We found evidence of a younger age for this planetary system, $t < 1.8$ Gyr, which is supported by both evolutionary tracks and gyrochronology. Finally, we confirm the detection of the optical secondary eclipse by Désert et al. and also find the brightness phase variation with the Q1 and Q2 Kepler data. The latter indicates a low redistribution of stellar heat to the night side (<16% at 1-σ), if the optical planetary occultation comes entirely from thermal flux. The geometric albedo is $A_g < 0.12$ (1-σ).

1. Introduction

For two years and a half, the Kepler space telescope has been monitoring the optical flux of about 156,000 stars with 9 < $V$ < 16 in the Cygnus constellation to search for transiting planets (e.g., Borucki et al. 2006). More than 1200 planetary candidates were announced by Borucki et al. (2011) in February 2011. However, all of them cannot be followed up by the Kepler team because it would require a huge amount of telescope time. Since the Kepler team publicly announced all the planetary candidates they found, this allows other groups to carry out spectroscopic observations of their targets.

The SOPHIE spectrograph (Bouchy et al. 2009), mounted on the 1.93 m telescope at the Observatoire de Haute Provence (France), has been performing very well to assess the nature of CoRoT planetary candidates and derive the orbital parameters of many CoRoT planets (e.g., Deleuil et al. 2011). Therefore, about one and a half years ago, we started the spectroscopic follow-up of Kepler candidates with Jupiter and Saturn sizes, around stars with $K_0^1 \leq 14.7$. So far, this follow-up campaign has led to several interesting discoveries: one new hot Jupiter orbiting an evolved star, KOI-428b (Santerne et al., 2010); KOI-423b, an 18 $M_{\text{Jup}}$ companion orbiting a subgiant F7IV star, which could be either a low-mass brown dwarf or an extremely massive planet (Bouchy et al., 2011); and the hot Jupiter KOI-196b for which we detected the optical secondary eclipse and phase variations (Santerne et al., 2011). Moreover, this follow-up campaign reveals the rate of Kepler Jupiter-size planetary candidates that are actually false positives, to be compared with the ~8% upper limit predicted by Morton & Johnson (2011) (Santerne et al., in prep.).

In the present paper, we announce the discovery of two new hot Jupiters with orbital periods of ~3 days, namely KOI-135b and KOI-204b. Orbital and planetary parameters for these two planets were derived by performing a simultaneous modelling

* Based on observations made with SOPHIE on the 1.93-m telescope at Observatoire de Haute-Provence (CNRS), France.

1 Kepler magnitude.
of Kepler photometry and SOPHIE radial-velocity observations. Moreover, independently of the Kepler team, we confirm the planetary nature of Kepler-17b, a hot Jupiter around an active solar-like star, recently announced by Désert et al. (2011). Our new SOPHIE spectra, which are used both to measure the radial-velocity variations and characterise the host star, allowed us to improve the parameters of this planetary system. Besides that, we detected the optical phase variation of Kepler-17b, i.e. the variation in brightness as the dayside of the planet rotates into and out of view. It has not been reported previously, so we discuss the possible implications for the planet atmosphere.

2. KOI-135

2.1. Kepler observations

KOI-135 is a $K_p = 14.0$ star that was observed by Kepler with a temporal sampling of 29.4 min (Long Cadence data) for 122.2 days: from 2009 May 13 to June 15 during the first 33.5-day segment of science operations (Q1); and from June 20 to September 16 of the same year, during the second quarter (Q2) data covering 88.7 days. Its coordinates, magnitudes and IDs are listed in Table 1. The raw Kepler light curve, publicly available at the MAST archive\(^2\), contains 5722 validated photometric measurements. From these data points we subtracted the flux excess due to background stars contaminating the photometric mask, as estimated by the Kepler team: 2.4% for the Q1 and 3.1% for the Q2 data\(^3\). Long-term trends of clear instrumental origin and the steep variations after the two safe modes (Jenkins et al. 2010) were then removed. The thus treated light curve is shown in Fig. 1. It exhibits 39 transits with a period of 3.02 days, a depth of 0.8%, and a duration of $\sim 3$ h. The standard deviation in the light curve, computed in a robust way after removing low-frequency variations with a sliding median filter, is 180 ppm, which is compatible with the median of the errors of the single photometric measurements, i.e. 160 ppm.

Stellar variability due to the rotational modulation of active regions on the stellar photosphere is clearly visible in the light curve (Fig. 1). Its peak-to-peak amplitude is about 0.5%. After removing transits, we performed a periodogram analysis of the light curve and computed the autocorrelation function in order to estimate the stellar rotation period. The two methods give very consistent results: $P_{\text{rot}} = 12.9 \pm 0.7$ days.

2.2. Centroid analysis

To reject the scenario of a background eclipsing binary located within the Kepler photometric mask, which might mimic the observed transits, the centroid timeseries was analysed (Batalha et al. 2010). KOI-135 does not show any significant centroid shift during the transit up to 0.07 mapixel (Fig. 2).

2.3. Ground-based follow-up

2.3.1. Radial-velocity observations

Eight spectra of KOI-135 were secured in July, August, and September 2011 with the SOPHIE spectrograph. They were acquired in high-efficiency mode (resolution power $R = 39 000$ at

\(^3\) http://archive.stsci.edu/kepler/kepler_fov/search.php
5500 Å) and slow mode for reading the detector. The first aperture fiber was put on the target whereas the second 2′ away on the sky to evaluate the background. The spectra were extracted with the SOPHIE pipeline. Following the techniques described in Baranne et al. (1996) and Pepe et al. (2002), the radial velocities were measured from a weighted cross-correlation of the spectra with a numerical mask. We used a standard G2 mask that includes more than 3500 lines. The resulting cross-correlation functions (CCFs) were fitted by Gaussians to get the radial velocities and the associated photon-noise errors. The full width at half maximum of those Gaussians is 11.6 ± 0.1 km s⁻¹, and its contrast is 24 ± 2% of the continuum. We only used the spectral orders 12 to 38 in the cross-correlation to reduce the dispersion of the measurements produced by noisy spectral orders. Moonlight contamination was tenuous in the spectra and required a correction only for two over the eight spectra, following the method described in Hébrard et al. (2008) and Bonomo et al. (2010). It introduced modest corrections (7 and 20 m s⁻¹ for both spectra).

The log of the observations and the radial-velocity measurements are reported in Table 2. Radial-velocity precision ranges between 12 and 29 m s⁻¹ depending on the exposure time and weather conditions. Table 2 also lists the bisector spans that we measured on the cross-correlation functions in order to quantify the possible shape variations of the spectral lines. The error bars on the bisector spans were assumed to be twice those of the corresponding radial velocity.

The measurements are displayed in the left panel of Fig. 3, together with their circular Keplerian fit obtained from the global photometry and radial-velocity best fit (Sect. 2.4). The radial velocities present a semi-amplitude $K = 375 ± 13$ m s⁻¹, in phase with the Kepler ephemeris. The standard deviation of the residuals to the fit is $\sigma_{O-C} = 15.9$ m s⁻¹. The reduced $\chi^2$ is 1.0 for the eight radial velocities used in the fit. We do not detect any drift over the 55-day span of the radial velocity.

SOPHIE radial velocities obtained with different stellar masks (F0, K0, or K5) produce variations with the same amplitude as for the G2 mask and, thus, there is no indication for blend scenarios involving stars of different spectral types. Similarly, the CCF bisector spans show neither variations nor trend as a function of radial velocity (Fig. 4, left panel). This reinforces the conclusion that the radial-velocity variations are caused by a planetary companion and not by changes in the spectral line profile due to blends.

2.3.2. Stellar characterisation

Stellar parameters and iron abundances were derived in LTE, using a grid of plane-parallel, ATLAS9 model atmospheres (Kurucz 1993) and the 2002 version of the radiative transfer code MOOG (Sneden 1973). The methodology used is described in detail in Santos et al. (2004), Sousa et al. (2008), and references therein. The full spectroscopic analysis is based on the EWs of a set of 49 Fe i and 13 Fe ii weak lines, by imposing ionisation and excitation equilibrium, as well as a zero slope between the abundances given by individual lines and their equivalent width. The errors in the stellar parameters were derived using the same methodology as described in Gonzalez (1998).

The total $S/N$ of the SOPHIE spectra used for this analysis (co-added from several individual spectra used to derive radial-velocities) is 36 per pixel (0.02 Å) at 5500 Å. We subtracted the background sky light on the science spectra using the second SOPHIE aperture positioned on the sky. The EWs were carefully measured one by one using the IRAF splot routine.

For FGK dwarfs, the stellar parameters obtained using this methodology were shown to be compatible with other estimates in the literature. In particular, the derived effective temperatures are very close to the ones obtained using recent applications of the infrared flux method (Casagrande et al. 2006). For a recent comparison we refer to Sousa et al. (2011).

The atmospheric parameters for the host star KOI-135, determined with the described procedure, are $T_{\text{eff}} = 6041 ± 143$ K, $\log g = 4.64 ± 0.13$, and metallicity $\text{[Fe/H]} = 0.33 ± 0.11$. No detectable emission was found in the cores of Ca ii H & K lines. The $V$ sin $i_e$ of $5.5 ± 1.5$ km s⁻¹ is in agreement with the rotation period determined from the light curve, assuming a stellar inclination of $i_e \sim 90$ degrees.

2.4. System parameters

To derive the orbital and planetary parameters, a simultaneous fit of Kepler photometry and SOPHIE radial-velocity measurements was performed. All the transits were normalised by fitting a parabola to the 11 h intervals of the light curve before the ingress and after the egress of each transit. We discarded two of the thirty-nine available transits, specifically those occurring at 2 455 056.139 and 2 455 089.404 BJD. Indeed, the out-of-transit intervals around these epochs were not wide enough to correctly normalise the transits.

The nine free parameters of our global best fit are the orbital period $P$, the transit epoch $T_{\text{eq}}$, the transit duration $T_{14}$, the ratio of the planet to stellar radii $R_p/R_*$, the inclination $i$ between the orbital plane and the plane of the sky, the Lagrangian orbital elements $h = e \sin \omega$ and $k = e \cos \omega$ where $e$ is the eccentricity and $\omega$ the argument of the periastron, the radial-velocity semi-amplitude $K$, and the systemic radial velocity $\gamma_{\text{sys}}$. The two non-linear limb-darkening coefficients $u_0 = u_0 + u_{0.4}$ and $u_4 = u_4 - u_0$ were fixed in our analysis. They cannot be left as free parameters because the orbital period is almost an integer multiple of the long-cadence sampling $\delta t = 29.42$ min, $P = 147.986 \cdot \delta t$, which implies that the transit ingress and egress are not well sampled

$$u_0 \text{ and } u_4 \text{ are the coefficients of the limb-darkening quadratic law: } I(\mu)/I(1) = 1 - u_0(1 - \mu) - u_4(1 - \mu)^2, \text{ where } I(1) \text{ is the specific intensity at the centre of the disc and } \mu = \cos \gamma, \gamma \text{ being the angle between the surface normal and the line of sight.}$$

Notes. † Measurements corrected from Moonlight pollution.

Fig. 3. Upper panel: radial-velocity measurements of the three targets with 1-σ error bars as a function of time, together with their Keplerian fit (top) and residuals of the fit. Lower panel: same as above but as a function of the orbital phase.

The transit fitting was carried out using the model of Giménez (2006, 2009) and a denser temporal sampling δ\(t\)\(_{\text{model}}\) = δ\(t\)/5, as suggested by Kipping & Bakos (2011) to overcome the problem of the coarse Kepler sampling (see also Kipping 2010). The \(\chi^2\) of each trial model is then computed by binning the model samples at the Kepler sampling rate δ\(t\). The search for the best solution of our combined fit was performed by using the algorithm AMOEBA (Press et al. 1992) and changing the initial values of the parameters with a Monte-Carlo method to avoid the solution getting stuck at local minima. The 1-σ errors of the system parameters were estimated through a bootstrap procedure consisting in shifting the photometric residuals and, at the same time, shuffling the radial velocity ones. During the bootstrap procedure, the limb-darkening coefficients were allowed to

(see Fig. 5). The adopted limb-darkening coefficients \(u_a\) and \(u_b\) for the Kepler bandpass were taken from the Sing (2010) tables\(^5\), after linearly interpolating at the \(T_{\text{eff}}\), log \(g\) and metallicity of the star: \(u_a = 0.375 \pm 0.026\) and \(u_b = 0.277 \pm 0.015\), which give \(u_+ = 0.652 \pm 0.030\) and \(u_- = 0.098 \pm 0.030\).

The transit fitting was carried out using the model of Giménez (2006, 2009) and a denser temporal sampling \(\delta t_{\text{model}} = \delta t/5\), as suggested by Kipping & Bakos (2011) to overcome the problem of the coarse Kepler sampling (see also Kipping 2010). The \(\chi^2\) of each trial model is then computed by binning the model samples at the Kepler sampling rate \(\delta t\). The search for the best solution of our combined fit was performed by using the algorithm AMOEBA (Press et al. 1992) and changing the initial values of the parameters with a Monte-Carlo method to avoid the solution getting stuck at local minima. The 1-σ errors of the system parameters were estimated through a bootstrap procedure consisting in shifting the photometric residuals and, at the same time, shuffling the radial velocity ones. During the bootstrap procedure, the limb-darkening coefficients were allowed to

\(^5\) http://vega.lpl.arizona.edu/singd/David_Sing/Limb_Darkening.html
The stellar density derived from the transit fitting and the STAREVOL evolutionary tracks (Palacios, priv. comm.; Siess 2006), for the effective temperature and metallicity of KOI-135 point to a star with mass $M_\star = 1.32 \pm 0.09 \, M_\odot$ and radius $R_\star = 1.42 \pm 0.07 \, R_\odot$. The quoted errors on stellar parameters also take the uncertainties inherent in stellar models into account, which are typically 3% for the stellar radius and 5% for the mass (Southworth 2011; see also Sect. 4 in Désert et al. 2011). The latter were quadratically added to the statistical errors on $M_\star$ and $R_\star$ related to the stellar density from the transit best fit.

We point out that the surface gravity deduced from these stellar parameters, $\log g = 4.26 \pm 0.05$, is compatible with the spectroscopic $\log g$ at 2.7σ. However, it is well known that the surface gravity derived from a spectral analysis is the most uncertain atmospheric parameter and, thus, such an apparent discrepancy must not be of great concern. In other words, our error bars on the spectroscopic $\log g$ are likely underestimated. Fixing the $\log g$ to the photometric determination and again performing the spectral analysis letting only the $T_{\text{eff}}$ and metallicity vary, changes the solution reported in Sect. 2.3.2 only slightly, well within the 1-σ uncertainties.

According to the determined stellar parameters, the mass and radius of the hot Jupiter KOI-135b are $M_p = 3.23 \pm 0.19 \, M_{\text{Jup}}$ and $R_p = 1.20 \pm 0.06 \, R_{\text{Jup}}$. The corresponding planet density is $2.33 \pm 0.36 \, \text{g cm}^{-3}$. The STAREVOL evolutionary tracks indicate that the age of the star, hence of the planetary system KOI-135, is $2.8_{-0.8}^{+1.0} \, \text{Gyr}$. This age is in good agreement with the estimate given by gyrochronology (Barnes 2007), i.e. $1.6 \pm 0.7 \, \text{Gyr}$.

We point out that the agreement is even better when considering the "modified gyrochronology" by Lanza (2010), which takes the influence of the planet on the evolution of stellar angular momentum into account and gives $3.0 \pm 1.3 \, \text{Gyr}$.

3. KOI-204

3.1. Kepler observations

The target KOI-204 is a faint star with Kepler magnitude $K_p = 14.7$. Its coordinates, magnitudes and IDs are listed in Table 1. As for KOI-135, only Q1 and Q2 raw light curves were considered. From these curves the flux excess due to contaminating background stars, which is 4.4% for Q1 and 6.0% for Q2 data, was subtracted. The KOI-204 light curve, displayed in Fig. 6, shows 35 transits with a period of 3.2 days, a depth of 0.74%, and a duration of 3 h. Long-term variations with an amplitude of ~1% are also seen in the light curve, indicating that the star KOI-204 is a slow rotator. After filtering out such variations, the rms of the light curve is 370 ppm, compatible with the median of the errors of the individual photometric measurements, i.e. 340 ppm.

6 Using $B - V = 0.58 \pm 0.04$ estimated from Eq. (3) in Sekiguchi & Fukugita (2000).

Notes. | (a) The non-linear limb-darkening coefficients were fixed for the transit fitting but allowed to vary within their 1-$\sigma$ error bars during the bootstrap procedure (see text for explanation); (b) from Kepler photometry and evolutionary tracks; (c) from STAREVOL evolutionary tracks; (d) black body equilibrium temperature assuming a uniform heat redistribution to the night-side.

3.2. Centroid analysis

KOI-204 presents a hint of centroid effect with a shift of 0.72 ± 0.58 mpx in $X$ and 0.66 ± 0.54 mpx in $Y$ (see Fig. 2). According to the MAST database, the main contaminant is the star KIC9305838 with Kepler magnitude $K_p = 16.6$, located 8" N from KOI-204. To confirm that the transits visible in the Kepler light curve occur on the main target KOI-204, we performed a photometric follow-up of this planetary candidate.

3.3. Ground-based follow-up

3.3.1. Photometric observations

The transit of KOI-204b was observed from the ground during the night of 2011 October 1, with a 14-inch telescope at the Obersky Observatory, La Palma. Seventy-four photometric measurements were obtained with a CCD SBIG STL-1001e, using a Sloan $r'$ filter and exposure time of 180 s. The angular pixel size is 1.15 arcsec. To keep the observed stars on the same pixel the whole night, we used a tip-tilt SBIG AOL. Photometric observations were reduced using the free software Munipack\(^b\) and are displayed in Fig. 7. They clearly show a transit occurring on the star KOI-204 that is compatible with those observed by Kepler.

3.3.2. Radial-velocity observations

Seven radial velocities of KOI-204 were secured with the SOPHIE spectrograph. The instrumental mode and measurement extractions were the same as those presented in Sect. 2.3.1. The full width at half maximum of the fitted CCFs is

\(^b\) [http://c-munipack.sourceforge.net](http://c-munipack.sourceforge.net)
The precision ranges between 16 and 46 m s$^{-1}$ and is relatively modest (20 m s$^{-1}$). The semi-amplitude of the radial-velocity variation of 419 m s$^{-1}$ at 1σ level.

3.3.3. Stellar characterisation

To derive the atmospheric parameters, the eight SOPHIE spectra taken to measure the radial-velocity variations were co-added, after subtracting the background sky light from each spectrum. This allowed us to obtain a single spectrum with a S/N of 25 per pixel (0.02 Å) at 5500 Å. Following the same methodology as described in Sect. 3.2.2, we determined the atmospheric parameters of the host star $T_{\text{eff}} = 5757 \pm 134$ K, log $g = 4.59 \pm 0.14$, and metallicity [Fe/H] = 0.26 ± 0.10. Moreover, no emission was observed in the cores of the Ca ii H&K lines, in agreement with the relatively quiescent light curve of KOI-204.

3.4. System parameters

System parameters and their 1-σ errors were derived in the same way as described in Sect. 2.4. They are listed in Table 3. The adopted limb-darkening coefficients for the Kepler bandpass and the spectral type of KOI-204 are $u_1 = 0.448 \pm 0.045$ and $u_0 = 0.227 \pm 0.029$ (Sing 2010). Figure 8 shows the phase-folded transit light curve and, overplotted, the transit best fit.

3.5. Stellar and planetary parameters

The mass and radius of the parent star, derived from the stellar density given by the transit best fit and STAREVOL evolutionary tracks, are $M_\ast = 1.19 \pm 0.10 M_\odot$ and $R_\ast = 1.52 \pm 0.09 R_\odot$. The uncertainties on stellar models were quadratically added to the statistical errors on the stellar mass and radius. As for KOI-135, the agreement between the spectroscopic and photometric log $g$ is at 3-σ level.

According to these stellar parameters, KOI-204b has a radius of 1.24 ± 0.07 $R_{\text{Jup}}$ and a mass of 1.02 ± 0.07 $M_{\text{Jup}}$, leading to a bulk density of $0.65 \pm 0.12$ g cm$^{-3}$. The age of the planetary system is estimated to be $6.95_{-1.3}^{+1.3}$ Gyr.

4. KOI-203 alias Kepler-17

Although fainter than $K_p = 14$, the planetary candidate KOI-203 was followed-up by the Kepler team that, using the high resolution spectrometer (HRS) at the Hobby-Eberly Telescope (HET), detected a radial-velocity variation of $419.5_{-15}^{+13}$ m s$^{-1}$, compatible with a planetary companion (Désert et al. 2011, hereafter...
D11). This hot Jupiter, renamed Kepler-17b, is interesting because it orbits an active solar-like star in 1.486 days and occults starspots during transits. Since the stellar rotation period of 11.9 days is almost an integer multiple of the orbital period, the short-cadence Kepler data (Q4-Q6) allowed D11 to see a “stroboscopic” effect: the spots are “mapped” by the planet each 45° in longitude. Moreover, since the planet occults the same spots for ~100 days, the true obliquity of the system, i.e. the angle between the stellar rotation axis and the normal to the orbital period, can be estimated close to zero (D11). Last but not least, the high quality of Kepler data allowed the Kepler team to detect the planetary occultation in the optical with a depth of 58 ± 10 ppm and, consequently, estimate the geometric albedo of Kepler-17b $A_g = 0.10 \pm 0.02$.

We independently followed up this candidate with the SOPHIE spectrograph. With new SOPHIE spectra, we are able to refine the orbital and stellar atmospheric parameters and, thus, to better characterise the planetary system.

### 4.1. Kepler observations

At the time of starting the radial-velocity follow-up, the public Kepler light curve contained only Q1 and Q2 data with the long-cadence rate. This light curve, corrected from the contamination flux and long-term trends of an instrumental origin, is shown in Fig. 9. Stellar variability due to photospheric magnetic activity has a peak-to-peak amplitude of ~3%. The long-cadence data, however, do not allow us to see the occultation of single spots by the planet during the transits, as observed by D11 with short-cadence data (one point per minute).

### 4.2. Ground-based follow-up

#### 4.2.1. Radial-velocity observations

Eight radial velocities of KOI-203 were secured with the SOPHIE spectrograph in April and May 2011, with the same instrumental mode and measurement extractions as described in Sect. 2.3.1. The full width at half maximum of the fitted CCFs is 10.8 ± 0.12 km s$^{-1}$, and its contrast is 34 ± 4 % of the continuum. Moonlight correction was applied to all but two measurements, but always remains below 25 m s$^{-1}$. The radial-velocity measurements are listed in Table 2. Their precision is between 13 and 35 m s$^{-1}$. Figure 3 (right panel) displays them, along with the circular Keplerian fit taking the period and transit epoch given by D11. This fit shows an acceptable reduced $\chi^2$ of 1.1 and a standard deviation of its residuals $\sigma_{O-C} = 17.8$ m s$^{-1}$, which indicates that there is no signature of stellar activity in the radial-velocity residuals. The derived semi-amplitude of the radial-velocity variation is $K = 391 \pm 11$ m s$^{-1}$. Here again, blend scenarios can be excluded because cross-correlations performed with F0, K0, and K5 masks give similar results to those obtained with the G2 mask, and CCF bisector spans are constant (Fig. 4, right panel). We thus concluded in May 2011 that KOI-203b is actually a transiting hot Jupiter.

Thanks to the radial velocities measured with the HRS spectrograph, D11 derive a slightly less accurate and larger semi-amplitude $K = 419.5^{+13.2}_{-15.0}$ m s$^{-1}$. Such radial velocities have uncertainties ranging between 26 and 199 m s$^{-1}$, which are significantly less precise than those obtained with SOPHIE. The residuals of the HRS Keplerian fit show a 52- m s$^{-1}$ dispersion (D11), to be compared with the 17.8-m-s$^{-1}$ dispersion obtained after the best fit of the SOPHIE data.

Our final result is obtained from the combined analysis of the SOPHIE and HRS data (excluding the least accurate HRS measurement) and is, however, mainly driven by the SOPHIE data. We derived $K = 399 \pm 9$ m s$^{-1}$. No significant radial-velocity drift was detected in the 275-day span of HET and SOPHIE data.

#### 4.2.2. Stellar characterisation

The SOPHIE spectrum, obtained by co-adding the eight individual spectra used for the analysis of radial-velocity variations, was used to derive the atmospheric parameters of the host star Kepler-17. Such a spectrum has $S/N = 31$ per pixel (0.02 Å) at 5500 Å, higher than the spectrum used by D11, i.e. $S/N = 17.5$. This allowed us to accurately determine the atmospheric parameters $T_{\text{eff}}, \log g$, and $[\text{Fe}/\text{H}]$. In contrast, D11 had to fix the log $g$ to the photometric value due to their low-quality spectrum (see D11, Sect. 3.1, for more details). We found a slightly hotter effective temperature than D11, $T_{\text{eff}} = 5781 \pm 85$ K, although compatible at 1.2σ. The metallicity $[\text{Fe}/\text{H}]$ and log $g$ are in good agreement with the values reported in D11: $[\text{Fe}/\text{H}] = 0.26 \pm 0.10$ and log $g = 4.53 \pm 0.12$. According to our atmospheric parameters, the $B-V$ of Kepler-17 is 0.66 ± 0.03 (Sekiguchi & Fukugita 2000), significantly lower than 0.82 as estimated by D11. As a consequence, the activity estimator $\log R'_{\text{HK}} = -4.47$ is higher than the value reported by D11, i.e. –4.61.

### 4.3. Stellar and planetary parameters

The transit fitting was performed in the same manner as for KOI-135b and KOI-204b (see Sect. 2.4) and our transit parameters were in very good agreement with those determined by D11. However, with much more Kepler data and especially short-cadence data, the error bars of D11 are significantly lower than ours, as expected. For that reason, in Table 4 we keep only the transit parameters and related 1-σ errors derived by D11.

From the transit density reported in D11 and STAREVOL evolutionary tracks for the atmospheric parameters of Kepler-17 (Sect. 4.2.2), the stellar mass and radius are estimated to be $M_\star = 1.16 \pm 0.06 M_\odot$ and $R_\star = 1.05 \pm 0.03 R_\odot$, respectively. From our value of $M_\star$ and the radial-velocity semi-amplitude $K$,
recomputed with the new SOPHIE measurements (Sect. 4.2.1), by considering a circular orbit and the orbital inclination given by D11, the planet mass is $M_P = 2.47 \pm 0.10 \, M_{\text{Jup}}$. The planet radius derived from the stellar radius and the value $R_P/R_\star$ reported in D11 is $R_p = 1.33 \pm 0.04 \, R_{\text{Jup}}$. All the stellar and planetary parameters are in good agreement with those determined by D11 (always within 1σ). Our slightly higher stellar mass compensates with the lower radial-velocity semi-amplitude giving almost the same planetary mass as D11.

The most striking difference concerns the age of the planetary system Kepler-17, which, according to our analysis, seems to be younger than 1.8 Gyr (at 1σ), while D11 find an age of 3.0 ± 1.6 Gyr. The age given by the evolutionary tracks can be compared to the age from the gyrochronology since the rotation period has been inferred from the light curve of Kepler-17: 0.9 ± 0.2 Gyr. The “modified gyrochronology” from Lanza (2010) points to an age of 1.7 ± 0.3 Gyr and thus is more consistent with the extreme limit of the age estimated from evolutionary tracks.

### 4.4. Secondary eclipse and phase variations of KOI-203b

Before the announcement of Kepler-17b by D11, we had independently detected its secondary eclipse and phase variations, although only with Q1 and Q2 Kepler data. This was the main reason we decided, as for KOI-196b (Santerne et al. 2011), to perform a spectroscopic follow-up of the Kepler planetary candidate KOI-203b.

To detect both the secondary eclipse and phase variations of Kepler-17b, transits were removed from the Q1 and Q2 light curves and the latter were divided into subsets of four days, approximately one third of the stellar rotation period. Each subset was then fitted separately with a fourth degree polynomial approximately one third of the stellar rotation period. Each subset was then fitted separately with a fourth degree polynomial. Before the announcement of Kepler-17b by D11, we performed such a detrending, the phase variation and secondary eclipse of Kepler-17b, transits were removed from the Q1 and Q2 light curves and the latter were divided into subsets of four days, approximately one third of the stellar rotation period. Each subset was then fitted separately with a fourth degree polynomial.

Table 4. KOI-203: planet and star parameters.

| Derived system parameters |  |
|---------------------------|--|
| $a/R_\star$ | 5.48 ± 0.02 Désert et al. (2011) |
| $R_P/R_\star (R_P/R_\star)^{-1}$ | 1.001 ± 0.020 Désert et al. (2011) |
| Stellar density $\rho_p$ [g cm$^{-3}$] | 1.415 ± 0.084 Désert et al. (2011) |
| Impact parameter $b$ | 0.268 ± 0.014 Désert et al. (2011) |

**Notes.** (a) From STAREVOL evolutionary tracks; (b) black body equilibrium temperature assuming a uniform heat redistribution to the night-side.
with a fifth degree polynomial, the rms is equal to 250 ppm and, thus, comparable to that obtained with fourth degree polynomials. This motivates our choice for the use of fourth degree polynomials. In any case, we point out that both the secondary eclipse and phase variations are also visible using third and fifth degree polynomials, although just barely in the first case because of the significantly increased rms.

The phase variations and secondary eclipse were modelled using Eq. (1) in Snellen et al. (2009):

\[ F(\phi) = 2z_{\mathrm{ev}} \cdot [1 + \sin(\phi)]^2 \cdot (1 - F_{N/D}) \cdot R_{\text{day}} + \psi(\phi)] \]

where \( \phi \) is the orbital phase, \( R_{\text{day}} \) the contrast between the planet day-side flux and the stellar flux, i.e. the depth of the secondary eclipse, \( F_{N/D} \) the ratio of night-side to day-side flux, and \( z_{\text{ev}} \) the stellar brightness. The model of the secondary eclipse \( \psi(\phi) \) was computed using the transit model of Giménez (2006) with no limb-darkening and two free parameters: \( R_{\text{day}} \) and the time of the secondary eclipse \( T_{\text{sec}} \). The duration of the planetary occultation was fixed to that of the primary transit.

The simultaneous best fit of the phase variations and secondary transit was carried out on the unbinned filtered light curve in the same way as described in Sect. 2.4.1, i.e. using a Monte Carlo method coupled with the downhill simplex algorithm to search for the global minimum of the \( \chi^2 \). As for the transit fitting, we oversampled our model (Eq. (1)) with a temporal cadence five times denser than the Kepler sampling rate. The error bars of the fitted parameters were estimated with a bootstrap procedure that subtracts the best solution to the data, shifts the residuals in time, adds the subtracted solution, and performs the best fit again. Our \( \chi^2 \) analysis gives \( R_{\text{day}} = 52 \pm 21 \) ppm, \( F_{N/D} = 0 \) with an upper limit \( F_{N/D} < 0.16 \) at \( 1 \sigma \), \( z_{\text{ev}} = 0.999973 \pm 0.000011 \), and \( T_{\text{sec}} = 2454.9665361 \pm 0.0009 \) BJD, corresponding to an occultation phase of 0.5003 \pm 0.0006. The best fit is shown in Fig. 10 where we binned the data in bins of 0.03 in phase with the aim of displaying the phase variation and the secondary transit more distinctly. Our value of \( R_{\text{day}} \) is perfectly consistent with the occultation depth found by D11, i.e. \( 58 \pm 10 \) ppm, although our errors are obviously larger since we only have Q1 and Q2 data. The temperature of the secondary eclipse allows us to constrain \( -0.0005 < e \cos \omega < 0.0014 \) at 1-\( \sigma \), where \( e \) is the eccentricity and \( \omega \) the argument of periastron. This is compatible with a circular orbit, as also pointed out by D11. For this reason we fixed the eccentricity to zero in the analysis of the radial-velocity observations (Sect. 4.2.1).

By using the more precise occultation depth found by D11 and a Kurucz (1993) model spectrum for the star according to the atmospheric parameters given in Sect. 4.2.2, we estimated a brightness temperature \( T_{\text{d,Kepler}} = 2325 \pm 50 \) K in the Kepler bandpass. The planet day-side equilibrium temperature ranges from \( T_d = 1746 \pm 26 \) K assuming a uniform heat redistribution to the nightside (or, equivalently, a redistribution factor \( f = 1/4 \) in Eq. (1) of López-Morales & Seager 2007), to \( 2077 \pm 31 \) K for no redistribution (\( f = 1/2 \)). For the extreme case of a dynamics-free atmosphere, where the radiative timescale is shorter than the advective timescale, \( T_{d,\text{max}} = 2231 \pm 33 \) K (\( f = 2/3 \)).

Figure 11 shows the geometric albedo \( A_g \) within the 1-\( \sigma \) uncertainty (grey band) as a function of the planet day-side temperature. The dashed vertical lines indicate the values of \( T_d \) for the aforementioned redistribution factors \( f = 1/4, 1/2, \) and 2/3. As usual, \( A_g \) is estimated by assuming the planet radiates as a black body and adding a possible reflective component to match the observed occultation depth. However, the planet spectrum can significantly differ from a Planck curve and have a thermal emission in the optical that is stronger than expected from a simple black body (e.g., Fortney et al. 2008; Cowan & Agol 2011 and references therein; see also the discussion by Snellen et al. 2010 about the optical secondary eclipse of CoRoT-2b). Keeping this warning in mind, the geometric albedo, computed as explained above, is found between 0.01 and 0.12 (see Fig. 11).

Besides detecting the optical occultation in the Kepler light curve, D11 report the observations of the Kepler-17b secondary eclipse in the two Spitzer band-passes at 3.6 and 4.5 \( \mu \)m and derive brightness temperatures of \( T_{3.6,\mu m} = 1880 \pm 110 \) K and \( T_{4.5,\mu m} = 1770 \pm 150 \) K (see D11). If the planet day-side temperature ranges between the lower and upper limits of the Spitzer brightness temperatures, the geometric albedo would be \( 0.06 < A_g < 0.12 \). However, as pointed out by Cowan & Agol (2011), estimating the planet effective temperature with only two Spitzer wavebands can lead to errors on the true value up to 10% (see their Fig. 3). Therefore, \( T_d \) could be higher than the upper
limits given by $T_{3.6\,\mu m}$ and $T_{4.5\,\mu m}$, which would imply an even lower albedo, down to $A_g = 0$ if $T_d \approx T_{d,\text{Kepler}}$.

The phase variation we detected in the Kepler light curve including only Q1 and Q2 data tells us that, if all the flux from the planet seen in the optical is thermal in origin, then only a low fraction of stellar heat is transported to the night-side, less than 16% at 1-σ. In this case, the day-side temperature would be close to or higher than 1977 K. We found no evidence of a phase shift in the light curve, which is expected in the case of no redistribution, under the assumption that the optical occlusion comes entirely from the thermal flux.

As suggested by Cowan & Agol (2011), the observation of the thermal phase variation of Kepler-17b in one of the two IRAC bandpasses, if feasible for such a faint target, would in principle permit the night-side temperature to be estimated and, thus, would uniquely determine the circulation efficiency, the planet’s albedo, and its day-side temperature.

Finally, we would like to point out that our recomputed activity estimator $\log R'_{HK} = -4.47$ (Sect. 4.2.2), higher than the value given by D11, reinforces the propensity for no thermal inversion according to scenario proposed by Knutson et al. (2010) (see also Sect. 7.3 in D11).

5. Summary and conclusions

We reported the discovery of two new hot Jupiters, namely KOI-135b and KOI-204b, and independently of the Kepler team confirmed the planetary nature of KOI-203b alias Kepler-17b (Désert et al. 2011), thanks to radial-velocity measurements performed with the SOPHIE spectrograph at the Observatoire de Haute-Provence.

All three Jupiter-size planets orbit stars with super-solar metallicity, i.e. [Fe/H] ~ 0.3 dex. KOI-135b and KOI-204b have similar orbital periods, $P \sim 3$ days, and radius, $R_p \sim 1.2 R_{\text{Jup}}$, but different internal structures because their bulk densities differ by a factor of 4, $\rho_p = 2.33 \pm 0.36$ and 0.65 ± 0.12 g cm$^{-3}$, respectively. The density of Kepler-17b lies in between the two since it is equal to the Jupiter’s one within the error bars. The position of KOI-204b and Kepler-17b in the radius vs mass and mass vs orbital period diagrams of extrasolar planets are fairly common, being two slightly inflated planets. In contrast, with a mass of 3.23 ± 0.19 $M_{\text{Jup}}$, KOI-135b reaches the few known transiting planets with short orbital periods $P < 5$ days and masses between 2.5 and 5 $M_{\text{Jup}}$. Those that are more similar to KOI-135b, in terms of planetary radius and mass, are WASP-32b (Maxted et al. 2011) and HAT-P-16b (Buchhave et al. 2010).

We detected the optical phase variation of Kepler-17b in Q1 and Q2 long-cadence data and showed that the geometric albedo is $A_g < 0.12$. If all the optical occlusion is thermal, then our modelling of the phase variation indicates no redistribution of stellar heat to the night-side with an upper limit of 16% at 1-σ.

Finally, we pointed out that both Kepler-17 and KOI-135 are interesting targets for a detailed study of their photospheric magnetic activity by means of spot-modelling techniques (e.g., Lanza et al. 2007). The Kepler long-term photometry will permit activity cycles to be derived on time scales of a few years and, more easily, short-term spot cycles as found for CoRoT-2b (Lanza et al. 2009). In principle, this would also allow searches for possible star-planet magnetic interactions.

Acknowledgements. We thank the technical team at the Observatoire de Haute-Provence for their support with the SOPHIE instrument and the 1.93-m telescope and in particular the essential work of the night assistants. We are grateful to the Kepler team for giving public access to the corrected Kepler light curve and for publishing a list of good planetary candidates to follow-up. Financial support for the SOPHIE observations from the Programme National de Planétologie (PNP) of CNRS/INSU, France is gratefully acknowledged. We also acknowledge support from the French National Research Agency (ANR-08-JCJC-0102-01). A. S. Bonomo acknowledges CNES grant. N.C.S. acknowledges the support by the European Research Council/European Community through the FP7 through Starting Grant agreement number 239953, as well as from Fundação para a Ciência e a Tecnologia (FCT) through program Ciência 2007 funded by FCT/MEC (Portugal) and POPH/FSE (EC) and in the form of grants reference PTDC/CTE-AST/908528/2008 and PTDC/CTE-AST/908604/2008.
