Abstract
An extension of the adiabatic factorization of the time evolution operator is studied for spin in a general time-varying magnetic field $B(t)$. When $B(t)$ changes adiabatically, such a factorization reduces to the product of the geometric operator which embodies the Berry phase phenomenon and a usual dynamical operator. For a general time variation of $B(t)$, there should be a non-adiabatic operator in the factorization that is responsible for non-adiabatic transitions. A simple and explicit expression for the instantaneous angular velocity of the non-adiabatic operator is derived. This is done in a way that is independent of any specific representation of spin. Two classes of simple conditions are given under which the non-adiabatic operator itself can be made explicit. These conditions are used to find new expressions for $B(t)$ that allow the explicit construction of the time evolution operator.

1. Introduction

The purpose of this paper is to study a unique factorization of the time evolution operator for spin in a general time-varying magnetic field that should be seen as a generalization of the adiabatic factorization.

Let us first recall that in the proof of the quantum adiabatic theorem as presented in standard texts such as Messiah [1], a path-dependent operator $A(t)$ and a dynamical operator $D(t)$ are successively extracted from the time evolution operator. Then, there is left a non-adiabatic operator $N(t)$, the product of which with $A(t)$ and $D(t)$ should equal the time evolution operator $U(t)$, i.e. $U(t) = A(t)D(t)N(t)$. The rest of the proof of the quantum adiabatic theorem amounts to the proof of the statement that $N(t)$ approaches the identity operator in the adiabatic limit. The nature of the path-dependent operator has been clarified with the concept of the geometric phase [2–4]. Near the adiabatic limit, the non-adiabatic operator can be analyzed...
in the spirit of perturbative analysis [5–7]. For a general time variation of the parameters in the Hamiltonian, the non-adiabatic operator in the time evolution operator is responsible for transitions among instantaneous eigenstates. While the operator $A(t)$ is characterized by the geometry of the path traversed by the set of parameters in the Hamiltonian, and $D(t)$ is the usual dynamical operator, a simple characterization of the operator $N(t)$ that corresponds to a general time variation of the parameters in the Hamiltonian seems to be much less understood.

This paper intends to clarify the structure of the operator $N(t)$ for spin in a general time-varying magnetic field from a perspective that is independent of perturbation theory. The question we ask is how the geometry of the path of the direction of the magnetic field and the dynamical effect contribute in determining $N(t)$, which, like the operators $A(t)$ and $D(t)$, is an $SU(2)$ rotation. We shall find that the instantaneous angular velocity of $N(t)$ can be simply and explicitly determined in terms of three functions: an angle parameter naturally associated with the geometry of the path, a dynamical angle that characterizes $D(t)$ and the speed function that describes how the path is traversed in time. These three functions in turn can be explicitly expressed in a simple way in terms of $B(t)$. The factorization of the time evolution operator $U(t)$ derived here can be applied to the most general time variation of the magnetic field, including the adiabatic scenario and the sudden change scenario as special cases. Through this factorization of $U(t)$, we find that there exist new explicit solutions of time evolution that go beyond the scope of perturbative analysis.

In a certain sense, the approach we adopt in this paper differs from the traditional adiabatic perturbation theory (see, for example, [6] for a review). Let us observe that in the proof of the adiabatic theorem [1], the path-dependent operator is formally constructed out of the energy eigenstates, i.e.

$$A(t) = \sum_m |\psi_m(t)\rangle\langle\psi_m(0)|,$$

where $|\psi_m(t)\rangle$ is the instantaneous eigenstate of $H(t)$ that satisfies

$$\langle\psi_m(t)|\dot{\psi}_m(t)\rangle = 0.$$

Such a formal expression in terms of eigenstates is necessary because in the general situation no specific information of the Hamiltonian is available. The traditional adiabatic perturbation theory is strongly influenced by the use of instantaneous eigenstates. While such an approach is quite general in nature and have wide applications, it can also lead to complicated calculations and the results obtained from such an approach cannot be extrapolated to situations that are not within the scope of perturbation theory. We are of the view that in analyzing a specific problem such as the spin in a time-varying magnetic field, the use of energy eigenstates can be avoided and that the time evolution can be studied by exploring the algebraic structure of the Hamiltonian alone in constructing a factorization of the time evolution that can then be applied to any representation.

The Hamiltonian for a spin $S$ with magnetic moment $-k S$ in a time-varying magnetic field is

$$H = k \mathbf{B}(t) \cdot \mathbf{S} = k B(t) \mathbf{n}(t) \cdot \mathbf{S},$$

where $k$ is a constant, $\mathbf{B}(t) = B(t) \mathbf{n}(t)$ is the magnetic field and $\mathbf{n}(t)$ is a unit vector.

If $\mathbf{B}(t)$ changes adiabatically, the time evolution operator takes the form

$$U_A(t) = A(t)D(t),$$

where

$$A(t) = T \exp \left(-i \int_0^t (\mathbf{n} \times \dot{\mathbf{n}}) \cdot \mathbf{S} \, d\tau \right),$$

$$D(t) = T \exp \left(i \int_0^t B(t) \mathbf{n}(t) \cdot \mathbf{S} \, d\tau \right).$$
\[ D(t) = \exp \left( -i \int_0^t k B(\tau) \mathbf{n}(0) \cdot \mathbf{S} \, d\tau \right). \] (6)

The operator \( A(t) \) is determined by the path traversed by the direction of the magnetic field \( \mathbf{n}(t) \) on the unit two-dimensional sphere. (We set \( \hbar = 1 \).)

For the spin-1/2 case, the operator \( A(t) \) is written in this way using Pauli matrices in Berry’s iterative approach to calculate non-adiabatic corrections to the geometric phase [5]. In the factorization of time evolution studied in the present paper, the two factors \( A(t) \) and \( D(t) \), and another factor \( N(t) \) to be derived later belong to an arbitrary finite-dimensional irreducible representation of \( SU(2) \), so the method and result here apply to any spin.

First, let us fix certain notations. Recall from the quantum mechanics of spin that the dot product in the Hamiltonian indicates an isomorphism between the three-dimensional vector space and the Lie algebra with a certain basis:

\[ \{ -iS_1, -iS_2, -iS_3 \} . \]

To be more specific, here \( \{ -iS_1, -iS_2, -iS_3 \} \) is a basis of an arbitrary finite-dimensional irreducible representation of the Lie algebra \( su(2) \). So, in effect, the operators that are concerned in this paper can be thought of as finite-dimensional square matrices.

Let \( e_1(t) \), \( e_2(t) \) and \( e_3(t) \) be the three orthogonal unit vectors determined by the differential equations

\[ \dot{e}_i(t) = (\mathbf{n} \times \dot{\mathbf{n}}) \times e_i(t), \] (7)

with \( i = 1, 2, 3 \), and the initial condition

\[ e_1(0) = \mathbf{n}'(0), \quad e_2(0) = \mathbf{n}(0) \times \mathbf{n}'(0), \quad e_3(0) = \mathbf{n}(0). \] (8)

where the prime in \( \mathbf{n}'(0) \) means derivative taken with respect to the arc length. The vectors \( e_1(t) \) and \( e_2(t) \) satisfy the condition \( e_1(t) \cdot e_2(t) = 0 \). When viewed as tangent vectors, they have the geometric meaning of being parallel transported along the curve \( \mathbf{n}(t) \) on the unit 2-sphere.

Let us define \( S_1, S_2 \) and \( S_3 \) as follows:

\[ S_1 = e_1(0) \cdot \mathbf{S}, \quad S_2 = e_2(0) \cdot \mathbf{S}, \quad S_3 = e_3(0) \cdot \mathbf{S}. \] (9)

In accordance with the quantum mechanics for spin, these operators are assumed to satisfy the usual commutation relations \( [S_k, S_l] = i\epsilon_{klm} S_m \).

Finally, the operator \( A(t) \) is, by definition, the solution to the differential equation

\[ \dot{A}(t) = (-i(\mathbf{n} \times \dot{\mathbf{n}}) \cdot \mathbf{S}) A(t), \] (10)

with the initial condition that \( A(0) \) is equal to the identity. Because \( \dot{A}^{-1} A + A^{-1} \dot{A} = 0 \), we have \( \dot{A}^{-1} = -A^{-1} \dot{A} A^{-1} \). Then it follows from the definition of \( A(t) \) that

\[ \dot{A}^{-1}(t) = A^{-1}(t)(i(\mathbf{n} \times \dot{\mathbf{n}}) \cdot \mathbf{S}). \] (11)

2. Mathematical framework

In this section, we give an introduction to the existing knowledge on the fundamental properties of the operator \( A(t) \) and also a rotation angle between two frames naturally associated with the path traversed by the magnetic field. This preparation clarifies the general factorization of time evolution completed in the next section.
2.1. Two properties of $A(t)$

It is well known [3] that the Berry phase has mathematical interpretations in terms of fundamental concepts in differential geometry and Lie groups. Here we review the relevant mathematics from the point of view of the operator $A(t)$. As we shall see, $A(t)$ plays an important role in deriving the general factorization of $U(t)$. The two important properties of $A(t)$ for our purposes are as follows.

**Property 1.** First, we have the following property of $A(t)$:

$$A^{-1}(t) \mathbf{e}_i(t) \cdot \mathbf{S} A(t) = \mathbf{e}_i(0) \cdot \mathbf{S} = S_i.$$  \hspace{1cm} (12)

To prove this, note that this clearly holds for $t = 0$ by definition of $A(t)$. Now it suffices to prove that the left-hand side is constant or its time derivative is zero. This can be verified by using the expressions for $\dot{A}(t)$ and $\dot{A}^{-1}(t)$, the equation $\dot{\mathbf{e}}_i(t) = (\mathbf{n} \times \dot{\mathbf{n}}) \times \mathbf{e}_i(t)$ and the formula $[\mathbf{a} \cdot \mathbf{S}, \mathbf{b} \cdot \mathbf{S}] = i(\mathbf{a} \times \mathbf{b}) \cdot \mathbf{S}$.

This property of $A(t)$ is best understood in terms of the adjoint representation of the Lie group $G$ generated (through the exponential map) by the Lie algebra with the basis $\{-iS_1, -iS_2, -iS_3\}$. So $G$ is isomorphic to $SU(2)$ or $SO(3)$. In the case where $G$ is isomorphic to $SU(2)$, it is well known that this adjoint representation is a 2 to 1 covering map from $SO(3)$, and so in general the holonomy associated with the standard metric on the 2-sphere is insufficient in determining Berry phase information contained in $A(t)$. So the following property is indispensable if one wishes to cast the solid angle Berry phase from the point of view of $A(t)$.

**Property 2.** For any cyclic change of $\mathbf{n}(t)$ with $\mathbf{n}(T) = \mathbf{n}(0)$, we have $A(T) = \exp[-i\Omega(\mathbf{n}(0) \cdot \mathbf{S})]$, where $\Omega$ is the solid angle subtended by the closed path at the origin of the parameter space. Here the parameter is $\mathbf{B}$.

This is equivalent to associating a solid angle Berry phase with each individual energy eigenstate. To prove this property, let $|\psi_m(\mathbf{n}(0))\rangle$ be an initial eigenstate of $\mathbf{n}(0) \cdot \mathbf{S}$, i.e.

$$\mathbf{n}(0) \cdot \mathbf{S}|\psi_m(\mathbf{n}(0))\rangle = m|\psi_m(\mathbf{n}(0))\rangle.$$  \hspace{1cm} (13)

Then it can be shown, using property 1, that $|\psi_m(\mathbf{n}(t))\rangle = A(t)|\psi_m(\mathbf{n}(0))\rangle$ satisfies

$$\mathbf{n}(t) \cdot \mathbf{S}|\psi_m(\mathbf{n}(t))\rangle = m|\psi_m(\mathbf{n}(t))\rangle,$$  \hspace{1cm} (14)

Then $e^{i\gamma(t)}$ for a closed path can be calculated to be $e^{-i\Omega}$ by Berry’s phase two-form method. Since the $|\psi_m(\mathbf{n}(0))\rangle$’s form a complete basis for the representation space, it is clear that $A(T) = \exp[-i\Omega(\mathbf{n}(0) \cdot \mathbf{S})]$.

In conclusion, although the operator $A(t)$ has been written only as a time-ordered exponential, it nevertheless should be seen as an operator that can be explicitly constructed for a given representation of $SU(2)$ and for a given $\mathbf{n}(t)$. This can be seen as a consequence of the fact that the instantaneous angular velocity has the special form $(\mathbf{n} \times \dot{\mathbf{n}})$, so that the above two properties hold for $A(t)$. In a specific representation, one has $A(t) = \sum_m |\psi_m(\mathbf{n}(t))\rangle \langle \psi_m(\mathbf{n}(0))|$. Because the matrices $S_1$, $S_2$ and $S_3$ can now be written explicitly, one can obtain explicit solutions to the eigenvalue equation $\mathbf{n}(t) \cdot \mathbf{S}|\psi_m(\mathbf{n}(t))\rangle = m|\psi_m(\mathbf{n}(t))\rangle$. The condition $\langle \psi_m(\mathbf{n}(t))| \psi_m(\mathbf{n}(t))\rangle = 0$ then fixes a phase factor for the eigenfunction, and $A(t)$ can then be made explicit. This contrasts the non-adiabatic operator $N(t)$ to be discussed later: $N(t)$ can be made explicit only in special cases, although the instantaneous angular velocity of $N(t)$ has an explicit expression.
2.2. Relative rotation between two triads

In using an iterative method to calculate non-adiabatic corrections to the spin-1/2 geometric phase, Berry considered the relative rotation between the two triads \((\mathbf{e}_1(t), \mathbf{e}_2(t), \mathbf{e}_3(t))\) and \((\mathbf{n}'(t), \mathbf{n}(t) \times \mathbf{n}'(t), \mathbf{e}_3(t))\) [5]. The relation between the two triads can be expressed as

\[
\mathbf{e}_1(t) = \mathbf{n}(t) \cos \beta + \mathbf{n}(t) \times \mathbf{n}'(t) \sin \beta,
\]

\[
\mathbf{e}_2(t) = -\mathbf{n}'(t) \sin \beta + \mathbf{n}(t) \times \mathbf{n}'(t) \cos \beta.
\]

The condition \(\mathbf{e}'_1 \cdot \mathbf{e}_2 = 0\) then implies that

\[
\dot{\beta}(t) = -\left(\mathbf{n}(t) \times \mathbf{n}'(t)\right) \cdot \mathbf{n}''(t).
\]

So \(\beta(t)\) can be written as

\[
\beta(t) = \int_0^{l(t)} -\mathbf{n}'' \cdot (\mathbf{n} \times \mathbf{n}') \, ds,
\]

where \(l(t)\) is the arc length traveled through by \(\mathbf{n}(t)\). Thus, \(\beta(t)\) is a geometric quantity in the sense that it is determined by the path traversed by \(\mathbf{n}(t)\) on the 2-sphere and is independent of how the path is parameterized.

If \(l(t)\) increases with \(t\), then the relation between \(\mathbf{n}'(t)\) and the time derivative \(\dot{\mathbf{n}}(t)\) is

\[
\dot{\mathbf{n}}(t) = \mathbf{n}'(t) \left| \dot{\mathbf{n}}(t) \right|.
\]

Then we also have

\[
\dot{\beta}(t) = \int_0^t -\frac{\dot{\mathbf{n}}}{|\mathbf{n}|} \cdot (\mathbf{n} \times \mathbf{n}) \, dt.
\]

So \(\beta\) is explicitly determined if \(\mathbf{n}(t)\) is given.

3. General factorization of time evolution

In this section we study how the adiabatic factorization can be generalized when the magnetic field varies in a general way. The purpose is to derive an explicit expression of the angular velocity of the non-adiabatic operator in terms of the relative rotation \(\beta(t)\), which is a geometric quantity, and the dynamical quantity \(\phi(t) = -\int_0^t k B(\tau) \, d\tau\) in a way that is independent of specific representations of spin.

Let the non-adiabatic operator be \(\mathcal{N}(t)\) so that the time evolution operator in the general situation is

\[
U(t) = \mathcal{A}(t)D(t)\mathcal{N}(t).
\]

Substituting this expression into the Schrödinger equation

\[
i\dot{U}(t) = H(t)U(t),
\]

we obtain

\[
i\mathcal{A}^{-1}\dot{\mathcal{A}}\mathcal{N} + i\dot{\mathcal{D}} + i\mathcal{D}\dot{\mathcal{N}} = \mathcal{A}^{-1}H\mathcal{A}\mathcal{D}\mathcal{N}.
\]

By the first property of the operator \(\mathcal{A}(t)\) from the last section, it is clear that \(i\mathcal{D}\mathcal{N} = \mathcal{A}^{-1}H\mathcal{A}\mathcal{D}\mathcal{N}\), so that we have

\[
\mathcal{A}^{-1}\dot{\mathcal{A}}\mathcal{N} + \dot{\mathcal{D}}\mathcal{N} = 0
\]

or

\[
\mathcal{N} = -\mathcal{D}^{-1}\mathcal{A}^{-1}\dot{\mathcal{A}}\mathcal{N} = i\mathcal{D}^{-1}\mathcal{A}^{-1}(\mathbf{n} \times \dot{\mathbf{n}}) \cdot \mathbf{S}\mathcal{A}\mathcal{D}\mathcal{N}.
\]

This equation determines the operator \(\mathcal{N}(t)\) that satisfies the initial condition \(\mathcal{N}(0) = \mathcal{I}\).
To calculate $iD^{-1}A^{-1}(\mathbf{n} \times \mathbf{n}) \cdot \mathbf{SAD}$ in the above expression, let

$$\mathbf{n}(t) \times \mathbf{n}(t) = a(t) \mathbf{e}_1 + b(t) \mathbf{e}_2(t).$$

(25)

Then the relative orientation of the two triads from the last section states that

$$a(t) = |\mathbf{n}(t)| \sin \beta(t), \quad b(t) = |\mathbf{n}(t)| \cos \beta(t).$$

(26)

By property 1 for $A(t)$, we have

$$A^{-1}A = -i(a(t)\mathbf{S}_1 + b(t)\mathbf{S}_2).$$

(27)

Using the formulae

$$e^{i\phi \mathbf{S}_1} e^{i\phi \mathbf{S}_3} = \mathbf{S}_1 \cos \phi + \mathbf{S}_2 \sin \phi,$$

(28)

$$e^{i\phi \mathbf{S}_2} e^{i\phi \mathbf{S}_3} = \mathbf{S}_1 (-\sin \phi) + \mathbf{S}_2 \cos \phi,$$

(29)

we now have

$$-D^{-1}A^{-1}AD = i\alpha(t)(\mathbf{S}_1 \cos \phi + \mathbf{S}_2 \sin \phi) + \beta(t)(-\sin \phi) + \mathbf{S}_2 \cos \phi,$$

(30)

where

$$\phi(t) = -\int_0^t kB(\tau) \, d\tau.$$  

(31)

The expression for $-D^{-1}A^{-1}AD$ can now be written in the form

$$-D^{-1}A^{-1}AD = i\mathbf{S}_1|\mathbf{n}(t)| \sin[\beta(t) - \phi(t)] + i\mathbf{S}_2|\mathbf{n}(t)| \cos[\beta(t) - \phi(t)],$$

(32)

from which we get

$$N(t) = T \exp \left(-i \int_0^t (\omega_1(\tau)\mathbf{S}_1 + \omega_2(\tau)\mathbf{S}_2) \, d\tau \right),$$

(33)

where the two non-vanishing components of the instantaneous angular velocity are

$$\omega_1(t) = -|\mathbf{n}(t)| \sin[\beta(t) - \phi(t)], \quad \omega_2(t) = -|\mathbf{n}(t)| \cos[\beta(t) - \phi(t)].$$

(34)

The expression for $N(t)$ in terms of the explicitly determined angular velocity is the main result of this paper. Here $|\mathbf{n}(t)|$ has the simple meaning of being the velocity at which the path $\mathbf{n}$ on the 2-sphere is traversed in time. Together with $|\mathbf{n}(t)|$, the two naturally defined quantities $\beta(t)$ and $\phi(t)$, one geometrical and the other dynamical, provide a simple expression for the angular velocity which in turn completely determines the operator $N(t)$.

Since $\mathbf{S}_1$ and $\mathbf{S}_2$ can be expressed in terms of the raising and lowering operators $\mathbf{S}_+ = \mathbf{S}_1 + i\mathbf{S}_2$ and $\mathbf{S}_- = \mathbf{S}_1 - i\mathbf{S}_2$, $N(t)$ also can be written as

$$N(t) = T \exp \left(\int_0^t \left(\mathbf{S}_+ \mathbf{z}(t) \mathbf{S}_- - \mathbf{z}^\dagger(t) \mathbf{S}_- \right) \, d\tau \right),$$

(35)

where

$$\mathbf{z}(t) = \frac{|\mathbf{n}(t)|}{2} e^{i [\beta(t) - \phi(t)]}.$$  

(36)

In a certain sense, here $N(t)$ is analogous to the non-adiabatic operator that we derived for the Landau problem with a general time-dependent electric field, where it is a time-ordered coherent state displacement operator that describes inter-Landau level transitions. However, the time-ordered coherent state displacement operator there can be explicitly determined because the commutation relation $[a, a^\dagger] = 1$ is relatively simple. In fact, $N(t)$ for this time-varying Landau problem can be shown to be equal to a numerical phase factor times the ordinary exponential. In contrast, here the time-ordered exponential has no immediate relation to the ordinary exponential. This is due to the fact that we have a different commutation relation between $\mathbf{S}_+$ and $\mathbf{S}_-$, i.e. $[\mathbf{S}_+, \mathbf{S}_-] = 2\mathbf{S}_1$. We shall demonstrate below that $N(t)$ can be made explicit for special cases where additional conditions are specified.
4. Two classes of explicit factorizations

The general factorization includes previously studied cases such as the adiabatic approximation and the sudden approximation as special cases. It may also be applied to study in detail certain generalizations of the quantum adiabatic theorem such as when the parameter passes through the degeneracy point [9].

Let us take the sudden approximation for example. It states that if the parameters in the Hamiltonian change (even if appreciably) in a sufficiently short time, then under quite general conditions, the quantum state remains close to the initial state [1]. Suppose now that the magnetic field keeps its magnitude \( B \) constant but changes direction in a very short time; then the dynamical quantity \( \phi(t) = -\int_0^t kB(\tau) \, d\tau \) is close to zero (because \( t \to 0 \)) and thus can be ignored. Thus we have \( D(t) = 1 \). If \( \phi(t) = 0 \), we have

\[
N(t) = T \exp \left( -i \int_0^t (\omega_1(\tau)S_1 + \omega_2(\tau)S_2) \, d\tau \right),
\]

(37)

\[
= T \exp \left( i \int_0^t |\mathbf{n}(\tau)| \sin \beta(\tau)S_1 + |\mathbf{n}(t)| \cos \beta(\tau)S_2 \, d\tau \right),
\]

(38)

\[
= T \exp \left( i \int_0^t a(\tau)S_1 + b(\tau)S_2 \, d\tau \right).
\]

(39)

Thus we have

\[
\dot{N}(t) = (a(t)S_1 + b(t)S_2)N(t),
\]

(40)

\[
= ((\mathbf{n}(t) \times \dot{\mathbf{n}}(t)) \cdot \mathbf{e}_1(t))S_1 + (\mathbf{n}(t) \times \dot{\mathbf{n}}(t)) \cdot \mathbf{e}_2(t)S_2)N(t).
\]

(41)

On the other hand, by using property 1 in section 2, we have

\[
A^{-1}(t) = A^{-1}(t)(\mathbf{n} \times \dot{\mathbf{n}}) \cdot \mathbf{S},
\]

(42)

\[
= (A^{-1}(t)(\mathbf{n} \times \dot{\mathbf{n}}) \cdot \mathbf{S}A(t))A^{-1}(t),
\]

(43)

\[
= ((\mathbf{n}(t) \times \dot{\mathbf{n}}(t)) \cdot \mathbf{e}_1(t))S_1 + (\mathbf{n}(t) \times \dot{\mathbf{n}}(t)) \cdot \mathbf{e}_2(t)S_2)A^{-1}(t).
\]

(44)

Since \( N(t) \) and \( A^{-1}(t) \) satisfy the same differential equation with the same initial condition, they must be the same: \( N(t) = A^{-1}(t) \). From this we deduce that \( U(t) = 1 \). The factorization therefore recovers the sudden approximation as a special case.

The explicit form of the angular velocity of \( N(t) \) also suggests that \( N(t) \) itself can be made explicit under certain conditions that go beyond previously studied situations. Below we list two simple classes of explicit solutions of \( N(t) \).

(i) The operator \( N(t) \) is explicit if \( \beta(t) - \phi(t) \equiv 0 \). This condition can be written more explicitly, by the definitions of \( \beta(t) \) and \( \phi(t) \), as follows:

\[
kB(t) = -\frac{\dot{\mathbf{n}}(t)}{|\mathbf{n}(t)|^2} \cdot (\mathbf{n}(t) \times \dot{\mathbf{n}}(t)).
\]

(45)

The condition can be seen as putting no constraint on how \( \mathbf{n}(t) \) varies while giving \( B(t) \) explicitly for a given function \( \mathbf{n}(t) \). Therefore, there are infinitely many explicit examples that belong to this class. For instance, if \( \mathbf{n}(t) = (\sin \theta \cos \omega t, \sin \theta \sin \omega t, \cos \theta) \), then this condition automatically gives \( kB = -\omega \cos \theta \).

Under this condition, it is clear that \( N(t) \) becomes an ordinary exponential so that it is explicitly determined:

\[
N(t) = \exp \left( i \int_0^t |\mathbf{n}(\tau)|S_2 \, d\tau \right) = \exp(iS_2l(t)),
\]

(46)

where \( l(t) \) is the length of the path traversed by \( \mathbf{n}(t) \) on the unit sphere.
This class is clearly outside the scope of perturbative analysis. We recall that near the adiabatic limit, the dynamical angle changes much more rapidly than $\beta(t)$ does so that if the oscillating sine and cosine functions can make sure that $\int_0^t z(\tau) \, d\tau$ is small, then the small effect of $|n| \sim \epsilon$ does not accumulate during an adiabatic process with $t \in [0, 1/\epsilon]$ so that $N(t) \to 1$. The expression for $N(t)$ in this class of examples goes beyond adiabatic perturbation theory in that even if $|n(t)|$ is small, it may accumulate over time (because there are no oscillating factors in the intergrand) so that transitions among instantaneous eigenstates can be large. In fact, we see that in this case the transition probability among instantaneous eigenstates is characterized by the length of the path traversed by $n(t)$ at time $t$, and it is therefore a geometric quantity.

We note that, in general, $n(t)$ can be an arbitrary smooth curve on the 2-sphere and it is also possible that $B(t)$ changes sign during the time evolution. This only agrees with our assumption that the magnetic field is allowed to change in a general way which includes the situation where the magnetic field $B(t) = B(t)n(t)$ passes through the degeneracy point of the Hamiltonian. In order that $B(t)$ and $n(t)$ change smoothly, $B(t)$ is allowed to become zero and to change sign across the degeneracy point.

(ii) The second class of explicit solutions for $N(t)$ is obtained under the conditions that

$$n(t) = c_1, \quad \beta(t) - \phi(t) = c_2 t,$$

where $c_1$ and $c_2$ can be arbitrary constants. If these two conditions are satisfied, we have

$$N = ic_1(S_1 \sin c_2 t + S_2 \cos c_2 t) N = ic_1 e^{i c_2 S_1} S_2 e^{-i c_2 S_1}.$$

Let

$$N = e^{i c_2 S_1} N_1.$$

Then we have

$$\dot{N}_1 = (ic_1 S_2 - ic_2 S_1) N_1.$$

From this we see that $N_1$ is explicitly solved and an explicit expression for $N(t)$ is obtained:

$$N(t) = e^{i c_2 S_1} e^{i c_1 S_2 - i c_2 S_1}.$$

This class of explicit factorizations include as a special case the well-known exact solution developed specifically for analyzing the phenomenon of magnetic resonance [10]. In this case the function $n(t)$ is simply $n(t) = (\sin \theta \cos \omega t, \sin \theta \sin \omega t, \cos \theta)$, and we have $kB = -\omega \cos \theta - c_2$, which is an arbitrary constant. The traditional method for solving this special case is different from the factorization of time evolution we studied here. This is hardly surprising because this special solution was found long before the discovery of the geometric phase. Let us note that this special case also belongs to the first class if we choose $c_2 = 0$. Here, one must carefully distinguish between the condition $kB = -\omega \cos \theta$ and the traditional magnetic resonance condition. In the traditional magnetic resonance analysis, one considers transitions among energy levels along the direction $(0, 0, 1)$ fixed by a static magnetic field. The energy levels correspond to the static magnetic field only, not the total Hamiltonian, which also contains an oscillating magnetic field. In our notation, this static magnetic field is then $-kB \cos \theta$. (Let us assume $k < 0$ here.) The traditional magnetic resonance condition is $\omega = -kB \cos \theta$. The difference lies in that the condition $\omega = -kB \cos \theta$ is the resonance condition in the fixed direction, while the condition $kB = -\omega \cos \theta$ here represents an analogous resonance in the moving direction represented by $n(t)$, and the energy levels along $n(t)$ are determined by the whole instantaneous Hamiltonian. These two resonance conditions only agree with each other for small $\theta$. When $\theta$ is close to $\pi/2$, the dominating effect would
be transitions along the moving direction \( \mathbf{n}(t) \). It may be interesting to study in detail if the condition \( kB = -\omega \cos \theta \) can have experimental consequences.

We point out that there are new examples that belong to this class. Now we shall give a new explicit example of \( \mathbf{n}(t) \) and \( B(t) \) that satisfy equation (39). First we note that the condition \( \beta(t) - \phi(t) = c_2/\lambda^2 \) amounts to

\[
\frac{kB(t)}{\lambda^2} = \dot{\beta}(t) - \dot{c}_2 = -\frac{\mathbf{n}(t) \cdot (\mathbf{n}(t) \times \dot{\mathbf{n}}(t))}{|\dot{\mathbf{n}}(t)|^2} - c_2,
\]

so that we can focus on finding \( \mathbf{n}(t) \) that satisfies \( |\dot{\mathbf{n}}(t)| = c_1 \). Let us take

\[
\mathbf{n}(t) = (\sin \lambda t \cos \phi(t), \sin \lambda t \sin \phi(t), \cos \lambda t).
\]

Then it is easily shown that

\[
|\dot{\mathbf{n}}(t)|^2 = \lambda^2 + \dot{\phi}^2 \sin^2 \lambda t = c_1^2.
\]

(52)

For \( \lambda > 0, c_1^2 > \lambda^2 \) and \( 0 \leq t < \frac{\pi}{2\lambda} \), the solution for \( \phi(t) \) that satisfies \( \phi(0) = 0 \) can be found to be

\[
\phi(t) = \pm \frac{1}{\lambda} \sqrt{c_1^2 - \lambda^2} \ln \left( \tan \left( \frac{\lambda t}{2} + \frac{\pi}{4} \right) \right).
\]

(53)

From these solutions, \( kB(t) = -\frac{\mathbf{n}(t) \cdot (\mathbf{n}(t) \times \dot{\mathbf{n}}(t))}{|\dot{\mathbf{n}}(t)|^2} - c_2 \) is also explicitly known. In this example, it is clear that the curve \( \mathbf{n}(t) \) in general does not lie in a plane.

It could be of interest to find more examples within or beyond these two simple classes listed above and to investigate possible experimental manifestations of the solutions obtained.

5. Concluding remarks

The main purpose of this paper is to clarify \( N(t) \) for a much studied physical model: spin in a general time-varying magnetic field. Our motivation is to understand, in this specific example, the interplay between the geometric effect and the dynamical effect (as represented by the operators \( A(t) \) and \( D(t) \), respectively) in determining the structure of the non-adiabatic operator. Our main result is the explicit construction of the instantaneous angular velocity of \( N(t) \). This clarifies the structural information of \( N(t) \) and facilitates the study of transition probabilities among instantaneous eigenstates for a general time evolution. It puts \( N(t) \) on an equal footing with the operators \( A(t) \) and \( D(t) \) in the sense that the instantaneous angular velocities of all these operators are now explicitly known. With this structural information of \( N(t) \), we show that \( N(t) \) itself can be made explicit under two classes of simple conditions, both of them go beyond the scope of perturbation theory. This gives new physical examples of explicit functions of the magnetic field \( B(t) \) that correspond to the explicit construction of the time evolution operator.

The study of the extension of the adiabatic factorization of \( U(t) \) in the above spirit can be useful in other physical situations too. In a recent work, we examined the extension of the adiabatic factorization of the time evolution for the Landau problem with a spatially uniform electric field \( E(t) \) that has a general time dependence, including the situation where \( E(t) \) changes direction in time [8]. The factorization in this case shows that all the three factors can be determined explicitly: the non-adiabatic factor summarizes all non-adiabatic effects in the form of a path-ordered coherent state displacement operator, while the geometric operator is a path-ordered magnetic translation. The path-ordered operators imply the existence of two numerical phase factors that are quantum mechanical in nature. And a simple expression is obtained for non-adiabatic transitions among different energy levels (inter Landau level transitions) for a general time evolution using the non-adiabatic operator. The same problem can be analyzed from the point of view of constructing the quantum propagator (Green’s function) [11]. It seems, however, that it is in the Berry phase-type factorization of the time evolution operator that structural information regarding the time evolution is made transparent.
It could be of interest to study the factorization of time evolution for other physical systems, classical or quantum mechanical, where the same line of ideas applied here may contribute to the elucidation of the physical and/or mathematical aspects involved.
