Separating value functions across time-scales

Joshua Romoff 1 2  Peter Henderson 3 Ahmed Touati 4 2  Yann Ollivier 2  Emma Brunskill 3  Joelle Pineau 1 2

Abstract

In many finite horizon episodic reinforcement learning (RL) settings, it is desirable to optimize for the undiscounted return – in settings like Atari, for instance, the goal is to collect the most points while staying alive in the long run. Yet, it may be difficult (or even intractable) mathematically to learn with this target. As such, temporal discounting is often applied to optimize over a shorter effective planning horizon. This comes at the cost of potentially biasing the optimization target away from the undiscounted goal. In settings where this bias is unacceptable – where the system must optimize for longer horizons at higher discounts – the target of the value function approximator may increase in variance leading to difficulties in learning. We present an extension of temporal difference (TD) learning, which we call TD(Δ), that breaks down a value function into a series of components based on the differences between value functions with smaller discount factors. The separation of a longer horizon value function into these components has useful properties in scalability and performance. We discuss these properties and show theoretic and empirical improvements over standard TD learning in certain settings.

1. Introduction

The goal of reinforcement learning (RL) algorithms is to learn a policy that optimizes the cumulative reward (return) provided by the environment. A discount factor \( 0 \leq \gamma < 1 \) can be used to optimize an exponentially decreasing function of the future return. Discounting is often used as a biased proxy for optimizing the cumulative reward to reduce variance and make use of convenient theoretical convergence properties, making learning more efficient and stable (Bertsekas & Tsitsiklis, 1995; Prokhorov & Wunsch, 1997; Even-Dar & Mansour, 2003). However, in many of the complex tasks used for evaluating current state-of-the-art reinforcement learning systems (Mnih et al., 2013; OpenAI, 2018), it is more desirable to optimize for performance over long horizons. The optimal choice of discount factor, which balances asymptotic policy performance with learning ability, is often difficult, and solutions have ranged from scheduled curricula (OpenAI, 2018; Prokhorov & Wunsch, 1997; François-Lavet et al., 2015) to meta-gradient learning of the discount factor (Xu et al., 2018).

OpenAI (2018), for example, start with a small discount factor and gradually increase it to bootstrap the learning process. Rather than explicitly tackling the problem of discount selection, we make the observation that for any arbitrary discount factor, the discounted value function already encompasses all smaller timescales (discounts). This simple observation allows us to derive a novel method of generating separable value functions. That is, we can separate \( V_\gamma(s) \) into a number of partial estimators, which we call delta estimators \( (W_\gamma z) \), which approximate the difference between the value functions obtained with two discounts \( \gamma_z \) and \( \gamma_{z-1} \). Crucially, each \( W \) is learnable by itself, because it satisfies a Bellman-like equation based on the \( W \)'s of shorter horizons. Thus, these delta estimators can then be summed to yield the same discounted value function \( V_\gamma(s) \), and any subset of estimators from the series of smaller \( \gamma_z \) values. The use of difference methods (the delta between two value functions at different time scales) leads us to call our method TD(Δ).

The separable nature of the full TD(Δ) estimator allows for each component to be learned in a way that is optimal for that part of the overall value function. This means that, for example, the learning rate can be adjusted for each component (and similarly other parameters can be adjusted as well for that time scale), yielding overall faster convergence. Moreover, the components corresponding to smaller effective horizons can converge faster, bootstrapping larger horizon components (at the cost of some bias). Our method provides a simple drop-in way to separate value functions in any TD-like algorithm to increase performance in a variety of settings, particularly in MDPs with dense rewards. The intuitive method for setting intermediary \( \gamma_z \) values which we provide yields these performance gains without additional tuning in most cases. Yet, we also show that this method...
We also show how this method can be combined with and high performance gains in a simple ring MDP – used by Kearns & Singh (2000) for a similar bias-variance analysis – by adjusting the k-step returns used to update each delta estimator. We also show how this method can be combined with and TD(λ) (Sutton, 1988) and Generalized Advantage Estimation (GAE) (Schulman et al., 2015), leading to empirical gains in dense reward Atari games.

2. Related Work

Many recent works approach discount factors in different ways. To our knowledge, the closest work to our own is that of Sherstan et al. (2018), Sutton et al. (2011), Sutton (1995), Feinberg & Shwartz (1994), and Reinke et al. (2017), which learn ensembles of value functions at different time scales to form a generalized value function. In the case of Reinke et al. (2017), they do so for imitating the average return estimator. Feinberg & Shwartz (1994) examine an optimal policy for the mixture of two value functions with different discount factors. Similarly, Sutton (1995) present learning value functions across different levels of temporal abstraction through mixing functions. In the case of Sherstan et al. (2018) and Sutton et al. (2011), they train a value function such that it can be queried for a given set of timescales. However, we note that none of the aforementioned works utilize short term estimates to train the longer term value functions. Thus, while our method can similarly be used as a generalized value function, the ability to query smaller timescales is a side-benefit to the performance increases yielded by separating value functions into different time scales via TD(Δ).

Some recent work has investigated how to precisely select the discount factor choice (François-Lavet et al., 2015; Xu et al., 2018). François-Lavet et al. (2015) suggest a particular scheduling mechanism, seen similarly in OpenAI (2018) and Prokhorov & Wunsch (1997). Xu et al. (2018) propose a meta-gradient approach which learns the discount factor (and λ value) over time. All of these methods can be applied to our own as we do not necessarily prescribe a final overall γ value to be used.

Finally, another broad category of work relates to our own in a somewhat peripheral way. Indeed, hierarchical reinforcement learning methods often decompose value functions or reward functions into a number of smaller systems which can be optimized somewhat separately (Dietterich, 2000; Henderson et al., 2018a; Hengst, 2002; Reynolds, 1999; Menache et al., 2002; Russell & Zimdars, 2003; van Seijen et al., 2017). These works learn hierarchical policies, paired with the decomposed value functions, which reflect the structure of the goals.

3. Background and notation

Consider a fully observable Markov Decision Process (MDP) (Bellman, 1957) (S, A, P, r) with state space S, action space A, transition probabilities P : S × A → (S → [0, 1]) mapping state-action pairs to distributions over next states, and reward function r : (S × A) → R. At every timestep t, an agent is in a state s_t, can take an action a_t, receive a reward r_t = r(s_t, a_t), and transition to its next state in the system s_{t+1} ~ P(· | s_t, a_t).

In the usual MDP setting, an agent optimizes the discounted return: V^π(s) = \sum_{k=0}^{\infty} \gamma^k r_t[s_0 = s, \pi], where γ is the discount factor and π : S → (A → [0, 1]) is the policy that the agent follows. V^π can be obtained as the fixed point of the Bellman operator over the action-value function \( T^\pi V = r^\pi + \gamma P^\pi V \) where \( r^\pi \) and \( P^\pi \) are respectively the expected immediate reward and transition probabilities operator induced by the policy π.

The value estimate may be approximated via temporal difference (TD) learning (Sutton, 1988): given a transition \((s_t, a_t, r_t, s_{t+1})\) the value function estimate is updated according to \( \hat{V}_\gamma^\pi(s_t) \leftarrow \hat{V}_\gamma^\pi(s_t) + \alpha_t \delta_t^{V_\gamma^\pi} \) where \( \delta_t^{V_\gamma^\pi} := r_t + \gamma \hat{V}_\gamma^\pi(s_{t+1}) - \hat{V}_\gamma^\pi(s_t) \) is the TD error and \( \alpha \) is a learning rate. In a function approximation setting, we consider a parameterized value function \( \hat{V}_\gamma^\pi(\cdot; \theta) \). The estimate is updated according to the (semi-)gradient of the loss \( \mathcal{L}(\theta) = \mathbb{E} \left[ (y_t - \hat{V}_\gamma^\pi(s_t; \theta))^2 \right] \), where \( y_t = r_t + \gamma \hat{V}_\gamma^\pi(s_{t+1}; \theta_{old}) \) is the Bellman target, with \( \theta_{old} \) being the value function parameters before the update.

A number of works use TD learning to improve the performance of the policy through variance reduction baselines and other means. The most important for our experimental work is that of policy gradient methods (Sutton et al., 2000) and actor-critic methods (Konda & Tsitsiklis, 2000; Mnih et al., 2016). In actor-critic methods, the value function is updated per the TD error, and a stochastic parameterized policy (actor, \( \pi_a(s|a) \)) is learned from this value estimator via the advantage function where the loss is:

\[ \mathcal{L}(\omega) = \mathbb{E} \left[ - \log \pi(a|s, \omega) \left( r_t + \gamma \hat{V}_\gamma^\pi(s_{t+1}) - \hat{V}_\gamma^\pi(s_t) \right) \right] \]

Building on top of actor-critic methods, the Proximal Policy Optimization (PPO) (Schulman et al., 2017) method constrains the policy update to a given optimization region (a trust region) in the form of a clipping objective or a divergence penalty. The clipping objective for training a policy is:

\[ L^{CLIP}(\omega) = \mathbb{E} \left[ \min(\rho_t(\omega) \hat{A}_t, \text{clip}(\rho_t(\omega), 1 - \epsilon, 1 + \epsilon) \hat{A}_t) \right], \]
where the likelihood ratio is \( \rho_t(\theta) = \frac{\pi(\omega_t|s_t)}{\pi_{old}(\omega_t|s_t)} \) with \( \omega_{old} \) being the policy parameters before the update, \( \epsilon < 1 \) is some small factor applied to constrain the update, and \( \delta_t \) is the generalized advantage estimator:

\[
\hat{A}_t^{GA}(\gamma, \lambda) = \sum_{k=0}^{T-1} (\lambda \gamma)^k \delta_{t+k},
\]

(2)

where \( T \) is the maximum number of timesteps in an episode trajectory. The value function is updated through a slightly different loss in the PPO codebase (Schulman et al., 2017), as described by Ilyas et al. (2018):

\[
E \left[ (\hat{V}^\pi_\gamma(s; \theta) - (V^\pi_\gamma(s; \theta_{old}) + \hat{A}_t))^2 \right].
\]

(3)

4. TD(\( \Delta \))

In this section, we introduce the proposed TD(\( \Delta \)) method, along with several variations, including the multi-step case, a version compatible with TD(\( \lambda \)), and a version compatible with GAE. In the rest of the paper, we drop the subscript \( \pi \) in \( V^\pi \) to avoid clutter in the formulas.

4.1. Single Step TD(\( \Delta \))

Consider learning with \( Z + 1 \) different discount factors \( \gamma_0, \gamma_1, \ldots, \gamma_Z \). Each of these defines a corresponding value function \( V_{\gamma_z} \). We define the delta functions \( W_z \) by

\[
W_z := V_{\gamma_z} - V_{\gamma_{z-1}}, \quad W_0 := V_{\gamma_0}.
\]

(4)

This results in \( Z + 1 \) delta functions such that the desired \( V_{\gamma_z} \) is simply the sum of the previous delta functions:

\[
V_{\gamma_z}(s) = \sum_{i=0}^{z} W_i(s).
\]

(5)

We can derive a Bellman-like equation for the delta functions \( W \). Indeed, \( W_0 = V_0 \) satisfies the Bellman equation

\[
W_0(s_t) = E \left[ \gamma_0 W_0(s_{t+1}) \right],
\]

(6)

while the delta functions at larger time scales satisfy, at each state \( s_t \):

\[
W_z(s_t) = V_{\gamma_z}(s_t) - V_{\gamma_{z-1}}(s_t)
\]

\[
= E \left[ r_t + \gamma_z V_{\gamma_z}(s_{t+1}) - r_t + \gamma_{z-1} V_{\gamma_{z-1}}(s_{t+1}) \right]
\]

\[
= \gamma_z E \left[ W_z(s_{t+1}) + V_{\gamma_{z-1}}(s_{t+1}) \right] - \gamma_{z-1} V_{\gamma_{z-1}}(s_{t+1})
\]

\[
= \gamma_z W_z(s_{t+1}) + \gamma_{z-1} W_z(s_{t+1}),
\]

(7)

This is a Bellman-type equation for \( W_z \), with decay factor \( \gamma_z \) and rewards \( V_{\gamma_{z-1}}(s_{t+1}) \). Thus, we can use it to define the expected TD update for \( W_z \). Note that in this expression, \( V_{\gamma_{z-1}}(s_{t+1}) \) can be expanded as the sum of \( W_i(s_{t+1}) \) for \( i \leq z - 1 \), so that the Bellman equation for \( W_z \) depends on the values of all delta functions \( W_i, i \leq z - 1 \).

This way, the delta value function at a given timescale appears as an autonomous reinforcement learning problem with rewards coming from the value function of the immediately lower timescale. Thus, for a target discounted value function \( V_{\gamma_z}(s) \), we can train all the delta components in parallel according to this TD update, bootstrapping off of the old value of all the estimators. Of course, this requires assuming a sequence of \( \gamma_z \) values, including a largest and smallest discount \( \gamma_0 \) and \( \gamma_Z \). We will see in Section 6.2 that these can affect results, further allowing tuning. However, to avoid the addition of a number of hyperparameters, we assume a simple sequence where we double the effective discount \( \gamma \) at each time step. This simple sequence of \( \gamma_z \), without tuning, yields performance gains in many settings as seen in Section 6.2.

4.2. Multi-step TD(\( \Delta \))

In many scenarios, it has been shown that multi-step TD is more efficient than single-step TD (Sutton & Barto, 1998). We can easily extend TD(\( \Delta \)) to the multi-step case as follows. To begin, since \( W_0 := V_0 \), the multi-step target for \( W_0 \) is identical to the standard multi-step target with \( \gamma = \gamma_0 \). For all other \( W_z \), we can unroll both the bootstrap term and the rewards from the previous value function in Section 4.1. The TD target for \( W_0 \) and all other \( W_z \) are as follows:

\[
W_0(s_t) = E \left[ \sum_{i=0}^{K-1} \gamma_0^i r_{t+i} + \gamma_0^k W_0(s_{t+k}) \right],
\]

\[
W_z(s_t) = E \left[ (\gamma_z - \gamma_{z-1}) V_{\gamma_{z-1}}(s_{t+1}) + \gamma_z W_z(s_{t+1}) \right]
\]

\[
= E \left[ (\gamma_z - \gamma_{z-1}) r_{t+1} + \gamma_z V_{\gamma_z}(s_{t+1}) \right]
\]

\[
+ \gamma_z V_{\gamma_z}(s_{t+2})
\]

\[
= E \left[ (\gamma_z - \gamma_{z-1}) r_{t+1} + (\gamma_z - \gamma_{z-1}) V_{\gamma_{z-1}}(s_{t+2}) \right]
\]

\[
+ \gamma_z V_{\gamma_z}(s_{t+2})
\]

\[
= E \left[ (\gamma_z - \gamma_{z-1}) r_{t+1} + (\gamma_z - \gamma_{z-1}) V_{\gamma_{z-1}}(s_{t+2}) \right]
\]

\[
+ \gamma_z W_z(s_{t+2})
\]

\[
= \sum_{i=1}^{K-1} (\gamma_i - \gamma_{i-1}) r_{t+i} + (\gamma_k - \gamma_{k-1}) V_{\gamma_{k-1}}(s_{t+k})
\]

\[
+ \gamma_k W_z(s_{t+k}).
\]
Thus, each $W$ receives a fraction of the rewards from the environment. Additionally, each $W$ bootstraps off of its own value function as well as the value at the previous timescale. A version of this algorithm based on $k$-step bootstrapping from [Sutton & Barto (1998)] can be seen in Algorithm 1. We omit actions to simplify notation, though this approach can be used for any policy. We also note that while Eq. 8 has quadratic complexity w.r.t. $Z$, we can make the algorithm linear in implementation for large $Z$ by storing $V$ values at each timescale $\gamma_z$. This is the version we use for the ring MDP experiments in Section 6.

### 4.3. TD(\(\lambda\), \(\Delta\))

The traditional TD(\(\lambda\)) ([Sutton, 1984]) uses the following $\lambda$-return as a target for its update rules:

$$G_t^{V_{\lambda}} = \hat{V}_\gamma(s_t) + \sum_{k=0}^{\infty} (\lambda \gamma)^k \delta^{V_{\lambda}}_{t+k}.$$  

The underlying TD(\(\lambda\)) operator can be written:

$$T^n V = V + (I - \lambda \gamma P^n)^{-1}(T^n V - V)$$  

Similarly, for each $W$ we can define a $\lambda$ return:

$$G_t^{\hat{W}_z, \lambda} := \hat{W}_z(s_t) + \sum_{k=0}^{\infty} (\lambda \gamma)^k \delta^{\hat{W}_z}_{t+k},$$  

where $\delta^{\hat{W}_z}_t := \delta^{V_{\lambda}}_t$ and

$$\delta^{\hat{W}_z}_t := (\gamma_z - \gamma_{z-1})\hat{V}_{\gamma_{z-1}}(s_{t+1}) + \gamma_z \hat{W}_z(s_{t+1}) - \hat{W}_z(s_t),$$  

is the one step TD-error of our delta estimator.

### 4.4. TD(\(\Delta\)) with Generalized Advantage Estimation

GAE bears a strong resemblance to TD(\(\lambda\)). Since this method is used in powerful baselines ([Schulman et al., 2015; 2017]), we propose a version of TD(\(\Delta\)) which leverages GAE. Recall that [Schulman et al. (2017)] provide the GAE estimator target for a truncated trajectory as $A_t^{\text{GAE}(\gamma, \lambda)} = T_{t=0}^{t-1} (\lambda \gamma)^k \delta^{V_{\lambda}}_{t+k}$. To train our policy we use the same advantage function but replace the $\delta^{V_{\lambda}}_{t+k}$ with $\delta^{\Delta_{\lambda}}_{t+k}$ defined as:

$$\delta^{\Delta_{\lambda}}_{t+k} := r_t + \gamma \sum_{z=0}^{Z} \hat{W}_z(s_{t+1}) - \sum_{z=0}^{Z} \hat{W}_z(s_t),$$  

using the sum of all our estimators as a replacement for the value function. Thus, $A_t^{\Delta_{\lambda}} = T_{t=0}^{t-1} (\lambda \gamma)^k \delta^{\Delta_{\lambda}}_{t+k}$. We can also define a per-delta estimator $A_t^{\Delta_{\lambda}}$ advantage function, which we use to update the value function where $\delta^{\hat{W}_z}_t$ is from Eq. 11 such that $A_t^{\hat{W}_z} = T_{t=0}^{t-1} (\gamma_z \lambda_z)^l \delta^{\hat{W}_z}_{t+l}$. The delta functions are then updated with a loss:

$$\mathbb{E} \left[ (\hat{W}_z(s; \theta^{\hat{W}_z}) - (\hat{W}_z(s; \theta^{\hat{W}_z}_{old}) + \lambda A_t^{\hat{W}_z})^2 \right]$$  

These objectives can easily be applied to PPO by using the policy update from Eq. 1, replacing $\hat{A}_t$ with $A_t^{\Delta_{\lambda}}$. The delta estimators are updated according to Eq. 13. It is worth noting that the GAE target $\hat{W}_z(s; \theta^{\hat{W}_z}_{old}) + A_t^{\hat{W}_z}$ corresponds to a truncated version of the TD(\(\lambda\), \(\Delta\)) return in Eq. 10. Algorithm 2 shows an outline of the modified PPO algorithm using TD(\(\Delta\))-GAE which we use for Atari experiments.
5. Analysis

We now analyze our estimators more formally. The goal is that our estimator will provide favorable bias-variance trade-offs under some circumstances (as we shall see experimentally). To shed light on this, we first start by illustrating when our estimator is identical to the single estimator $\hat{V}_\gamma$ (Theorem 1) which gives insight into the important quantities of our estimator that can determine when we may achieve benefits over the standard $\hat{V}_\gamma$ estimator. Then motivated by these results and prior work by Kearns & Singh (2000), we bound the error of our estimator in terms of a variance and bias term (Theorem 4) that also yields insight into how to trade-off these quantities to achieve the best result.

5.1. Equivalence Settings and Improvement

In some cases, we can show that our TD($\Delta$) update and its variations are equivalent to the non-delta estimator $\hat{V}_\gamma$ when recomposed into a value function. In particular, we focus here on linear function approximation of the form:

$$\hat{V}_\gamma(s) := \langle \theta_{\hat{V}}, \phi(s) \rangle \text{ and } \hat{W}_z(s) := \langle \theta_{\hat{W}_z}, \phi(s) \rangle, \forall z$$

where $\theta_{\hat{V}}$ and $\{\theta_{\hat{W}_z}\}_z$ are weight vectors in $\mathbb{R}^d$ and $\phi : S \rightarrow \mathbb{R}^d$ is a feature map from a state to a given $d$-dimensional feature space. Let $\theta_{\hat{V}}$ be updated using TD($\lambda$) as follows:

$$\theta_{\hat{V}}^{t+1} = \theta_{\hat{V}}^t + \alpha \left( G_{\hat{V}}^{\gamma,\lambda} - \hat{V}_\gamma(s_t) \right) \phi(s_t), \quad (14)$$

where $G_{\hat{V}}^{\gamma,\lambda}$ is the TD($\lambda$) return defined in equation 8.

Similarly, each $\hat{W}_z$ is updated using TD($\lambda_z, \Delta$) as follows:

$$\theta_{\hat{W}_z}^{t+1} = \theta_{\hat{W}_z}^t + \alpha_z \left( G_{\hat{W}_z}^{\lambda_z} - \hat{W}_z(s_t) \right) \phi(s_t), \quad (15)$$

where $G_{\hat{W}_z}^{\lambda_z}$ is TD($\Delta$) return defined in equation 10. Here, $\alpha_z$ and $\{\alpha_z\}_z$ are positive learning rates. The following theorem establishes the equivalence of the two algorithms under some conditions.

**Theorem 1.** If $\alpha_z = \alpha, \lambda_z = \lambda, \forall z$ and if we pick the initial conditions such that $\sum_{z=0}^Z \theta_{\hat{W}_z}^0 = \theta_{\hat{V}}^0$, then the iterates produced by TD($\lambda$) (Eq. 14) and TD($\lambda_z, \Delta$) (Eq. 15) with linear function approximation satisfy:

$$\sum_{z=0}^Z \theta_{\hat{W}_z}^t = \theta_{\hat{V}}^t, \forall t, \quad (16)$$

(The proof is provided in the Supplemental.)

Note that the equivalence is achieved when $\lambda_z = \lambda, \forall z$. When $\lambda$ is close to one and $\gamma_z < \gamma$, the latter condition implies that $\lambda_z = \frac{\lambda}{\gamma_z}$ could potentially be larger than one. One would conclude that the TD($\lambda_z$) could diverge. Fortunately, we show in the next theorem that the operator TD($\lambda$) defined in equation 9 is a contraction mapping for $\lambda \in [0, 2]$ as long as $\lambda \gamma < 1$. Due to the correspondence between a truncated TD($\lambda$) update and GAE, mentioned in Section 4.4, it follows that this applies to the GAE value function update as well.

**Theorem 2.** $\forall \lambda \in [0, 2]$ such that $\lambda \gamma < 1$, the operator $T_\lambda^\pi$ defined as $T_\lambda^\pi V = V + (I - \lambda \gamma P^\pi)^{-1}(T^\pi V - V), \forall V \in \mathbb{R}^{S}$ is well defined. Moreover, $T_\lambda^\pi V$ is a contraction with respect to the max norm and its contraction coefficient is equal to $\frac{\gamma(1 - \lambda)}{1 - \gamma \lambda}$ (The proof is provided in the Supplemental.)

Similarly, we can consider learning each $W_z$ estimates using $k_z$-step TD($\Delta$) instead of TD($\lambda, \Delta$). In this case, the analysis of the theorem 1 could be extended to show that with linear function approximation, standard multi-step TD and multi-step TD($\Delta$) are equivalent if they both use same learning rate and $k_z = k, \forall z$.

However, we note that the equivalence with unmodified TD learning is the exception rather than the rule. For one, in order to achieve equivalence we require the same learning rate across every time scale. This is a strong restriction as intuitively the shorter timescales can be learned faster than the longer ones. Further, adaptive optimizers are typically used in the nonlinear approximation setting (Henderson et al., 2018c; Schulman et al., 2017). Thus, the effective rate of learning can differ depending on the properties of each delta estimator and its target. In principle, the optimizer can automatically adapt the learning to be different for the shorter and longer time scales, which we explore in Section 6.2.

Besides for the learning rate, such a decomposition allows for some particularly helpful properties not afforded to the non-delta estimator. In particular, every $W_z$ delta component need not use the same $k$-step return (or $\lambda$-return) as the non-delta estimator (or the higher $W_z$ components). In the case where $k_z = k, \forall z$ (or when $\gamma_z, \lambda_z = \gamma, \lambda, \forall z$) this will once again result in equivalence to the non-delta estimator with linear function approximation (see Supplementary Materials for the equivalence proofs). However, if $k_z < k_{z+1}, \forall z$ (or $\gamma_z, \lambda_z < \gamma_{z+1}, \lambda_{z+1}, \forall z$), then there is the possibility for variance reduction (at the cost of some bias introduction). We explore this further in Section 5.2.

5.2. Analysis for Reducing $k_z$ values

To see intuitively how our method differs from the single estimator case, let us consider the tabular phased version of k-step TD studied by Kearns & Singh (2000). In this setting, starting from each state $s \in S$, we generated $n$ trajectories $\{s_0^{(i)}, a_0^{(i)}, \ldots, s_k^{(i)}, a_k^{(i)}, r_k^{(i)}, s_{k+1}^{(i)}, \ldots\}_{1 \leq i \leq n}$ following policy $\pi$. For each iteration $t$, called also phase $t$,
the value function estimate for $s$ is defined as follows:

$$
\hat{V}_{\gamma,t}(s) = \frac{1}{n} \sum_{j=1}^{n} \left( \sum_{i=0}^{k-1} \gamma^i r_i(s^{(j)}_i) + \gamma^k \hat{V}_{\gamma,t-1}(s^{(j)}_k) \right)
$$

(17)

The following theorem from Kearns & Singh (2000) provides an upper bound on the error in the value function estimates defined by $\Delta_{\gamma} := \max_s |\hat{V}_{\gamma}(s) - V_{\gamma}(s)|$.

**Theorem 3.** (Kearns & Singh, 2000) for any $0 < \delta < 1$, let $\epsilon = \sqrt{\frac{2 \log(2k/\delta)}{n}}$, with probability $1 - \delta$,

$$
\Delta_{\epsilon} \leq \epsilon \left( \frac{1 - \gamma^k}{1 - \gamma} \right) + \gamma^k \Delta_{\gamma,t-1},
$$

(18)

(For completeness, we expand the original proof in the Supplemental.)

The first term $\epsilon \left( \frac{1 - \gamma^k}{1 - \gamma} \right)$, in the bound in Eq. 18, is a variance term arising from sampling transitions. In particular, $\epsilon$ bounds the deviation of the empirical average of rewards from the true expected reward. The second term is a bias term due to bootstrapping off of the current value estimate.

Similarly, we consider a phased version of multi-step TD($\Delta$). For each phase $t$, we update each $W$ component estimate as follows:

$$
\hat{W}_{\gamma,t}(s) = \frac{1}{n} \sum_{j=1}^{n} \left( \sum_{i=1}^{k-1} (\gamma_i - \gamma_{i-1}) r_i(s^{(j)}_i) 
+ (\gamma_i^k - \gamma_{i-1}^k) \hat{V}_{\gamma,t-1}(s^{(j)}_{t+k}) + \gamma_i^k \hat{W}_{\gamma,t-1}(s^{(j)}_{t+k}) \right)
$$

(19)

We establish now an upper bound on the error of phased TD($\Delta$) defined as the sum of error incurred by each $W$ components $\sum_{s=0}^{Z} \Delta_t \hat{W}_z$, where $\Delta_t \hat{W}_z = \max_s |\hat{W}_z(s) - W_z(s)|$.

**Theorem 4.** Assume that $\gamma_0 \leq \gamma_1 \leq \cdots \gamma_Z = \gamma$ and $k_0 \leq k_1 \leq \cdots \leq k_Z = k$, for any $0 < \delta < 1$, let $\epsilon = \sqrt{\frac{2 \log(2k/\delta)}{n}}$, with probability $1 - \delta$,

$$
\sum_{z=0}^{Z} \Delta_t \hat{W}_z \leq \epsilon \left( \frac{1 - \gamma^k}{1 - \gamma} \right) + \epsilon \sum_{z=0}^{Z-1} \gamma^k \Delta_{\gamma,t-1} + \epsilon \sum_{z=0}^{Z-1} \gamma^k \Delta_{\gamma,t-1}
$$

(20)

(The proof is provided in the Supplemental.)

Comparing the bound for phased TD($\lambda$) in theorem 3 with the one for phased TD($\Delta$) in theorem 4, we could conclude that the latter allow a variance reduction equal to $\epsilon \sum_{z=0}^{Z-1} \gamma^k \Delta_{\gamma,t-1}$ but it suffers from a potential bias introduction equal to $\sum_{z=0}^{Z-1} (\gamma^k - \gamma_{z-1}^k) \Delta_{\gamma,t-1} \geq 0$. This is due to the compounding bias from all shorter-horizon estimates. We note that in the case that $k_z$ are all equal, both terms cancel out and thus we obtain the same upper bound for both algorithms. It is a well known and often used result that the expected discounted return over $T$ steps is close to the infinite-horizon discounted expected return after $T \approx \frac{1}{1 - \gamma}$ (see for example the analysis in Kearns & Singh (2002)). Thus, we can conveniently reduce $k_z$ for any $\gamma_z$ such that $k_z \approx \frac{1}{1 - \gamma_z}$ so that we follow this rule. Thus, if we have $T$ samples, we can have an excellent bias-variance compromise on all timescales $< T$ by choosing $k_z = \frac{1}{1 - \gamma_z}$, so that $\gamma_z$ is bound by a constant (since $\gamma_z \frac{1}{1 - \gamma_z} \leq \frac{1}{2}$) for all $z$. This provides intuitive ways to set both $\gamma_z$ and $k_z$ values (as well as all other parameters) without necessarily searching. We can double the effective horizon at each increasing $W_z$ and similarly adjust all other parameters for estimation.

6. Experiments

For all experiments, the hyperparameter settings and extended details can be found in the Supplemental and all code is provided in: https://github.com/facebookresearch/td-delta. We follow the reproducibility checklist for machine learning research (Pineau, 2018) and provide all necessary additional descriptions in the Supplemental.

6.1. Tabular

![Figure 1](image1.png)

Figure 1. (Left) $\gamma_Z = 0.9375$, 250 random seeds on the 5-state ring MDP where the largest $k_Z = 32$. Error denotes the absolute error against the true discounted value function (pre-computed ahead of time using VI) averaged across the entire learning trajectory. Error bars denote standard error across random seeds. (Right) The average absolute error for the optimal learning rate at each $k$-step return up to the effective planning horizon of $\gamma_Z$.

We use the same 5-state ring MDP as in Kearns & Singh (2000) – a diagram of which is available in the Supplemen-
Figure 2. Each $W_z$ estimator for Amidar versus the reward of a policy on a single rollout trajectory. The drop-off around timestep 900 indicates a lost life and restart in the game.

tal for clarity – to demonstrate performance gains under decreasing $k$-step regimes as described in Section 5.1. For all experiments we provide a variable number of gammas starting with $\gamma Z = 0$ and increasing according to $\gamma_{z+1} = \frac{\gamma_z + 1}{2}$ until the maximum desired $\gamma Z$ is reached. Similarly, $k_z := \frac{1}{1-\gamma_z} + 1, \forall z$ as described earlier. The baseline is a single estimator with $\gamma = \gamma Z, k = k Z$. We run a grid of various $\gamma Z$ and $k Z$ values and use standard TD-style updates (Sutton, 1988) for our experiments.

We compare against the true error which can be calculated ahead of time using value iteration (VI) (Bellman, 1957). In the case where we do not tailor $k$ (all $k_z$ are equal), performance is exactly equal to the single estimator case due to the nature of the tabular updates (as in our proof, all terms exactly cancel out to yield the exact same estimator in this case). We compute the average error from the VI pre-computed optimal value function across the entire training trajectory and plot a sample of these results in Figure 1. We supply all results in the supplemental across a set of 7 different $\gamma$ values corresponding to effective planning horizons of (4, 8, 16, 32, 64, 125, 250). We note that performance gains tend to decrease as the largest $k Z$ grows past the effective planning horizon of the largest $\gamma Z$. However, consistent with the theory, in all cases we still perform about equal to (statistically) or significantly better than the single estimator setting.

6.2. Dense Reward Atari

We further demonstrate performance gains in Atari using the GAE-based version of TD($\Delta$). We directly update PPO with the TD($\Delta$)-GAE method, using the code of Kostrikov (2018). We compare against the standard PPO baseline with hyperparameters as found in (Schulman et al., 2017; Kostrikov, 2018). Our architecture differs slightly from the PPO baseline as the value function now outputs $Z + 1$ outputs (1 for each $W$). For complete fairness, we also add another neural network architecture which replicates the parameters of TD($\Delta$). That is, we use a neural network value function that outputs $Z + 1$ values which are summed together before computing the value loss (we call this PPO+). We run two versions of TD($\Delta$). The first version, as described in Section 4.4, uses the same set of $\gamma_z$ sequence as in the ring MDP experiments (starting at $\gamma_0 > .5$ for parity with GAE as aforementioned) where $\lambda_z$ is set for each lower $\gamma_z$ such that $\gamma_z \lambda_z = \gamma Z \lambda Z$ as per theorem 1. However, we note that due to the use of adaptive optimizers, performance may improve as parameters are honed for each delta estimator. Just as in the tabular setting where $k$ can be reduced for lower delta estimators, in this setting as well, parity with the baseline model is not necessary and $\lambda$ can effectively be reduced. To this end, we introduce a second version of TD($\Delta$)-GAE, where we limit any $\lambda_z$ s.t. $\lambda_z \leq 1$. We call this TD($\Delta$)-GAE-$\hat{\lambda}$ where $\lambda_z$ is the capped version of the re-scaled $\lambda_z$ value.

We run experiments on the 9 games defined in (Bellemare et al., 2016) as ‘Hard’ with dense rewards. We chose ‘Hard’ games as these games are most likely to need algorithmic improvements to solve. We chose dense reward tasks since we do not tackle the problem of exploration here (needed for tackling sparse reward settings), but rather modeling of complex value functions which dense reward settings are likely to benefit from. As seen in Table 1 (with average return across training and on hold-out no-op starts in the Supple-
ment), TD(\(\Delta\))-GAE performs (statistically) significantly better in a certain class of games roughly related to the frequency of non-zero rewards (the density). In both versions of TD(\(\Delta\))-GAE, the algorithms perform worse asymptotically than the baseline in two games, Zaxxon and Wizard of Wor, which belong to a class of games with lower density. Though TD(\(\Delta\))-GAE-\(\lambda\) performs somewhat better in both cases, as we see in Section 6.2, it is still possible to improve performance further in these games by tuning the number and scale of \(\gamma_z\) factors. One may wonder why performance improves in increasingly dense reward settings. There is a basic intuition that TD(\(\Delta\)) would allow for quick learning of short-term phenomena, followed by slower learning of long-term dependencies. Such a decomposition is reflected in a rolled out trajectory using the learned policy in Figure 2. There, the long-term \(W_z\) value declines early according to a consistent gradient towards a lost life in the game, while short-term phenomena continue to be captured in the smaller components like \(W_0\).

![Performance of different TD(\(\Delta\)) variations vs. the baselines on Zaxxon and WizardOfWor. ppo+ refers to ppo with an augmented architechture. ppoDelta refers to setting \(\gamma_z\lambda_z = \gamma\lambda\) \(\forall z\). ppoDelta3 and ppoDelta12 only use two value functions with horizons (3, 100) and (12, 100) respectively. Shaded region is standard error across 10 random seeds.](image)

Figure 3. Performance of different TD(\(\Delta\)) variations vs. the baselines on Zaxxon and WizardOfWor. ppo+ refers to ppo with an augmented architecture. ppoDelta refers to setting \(\gamma_z\lambda_z = \gamma\lambda\) \(\forall z\). ppoDelta3 and ppoDelta12 only use two value functions with horizons (3, 100) and (12, 100) respectively. Shaded region is standard error across 10 random seeds.

**Tuning and Ablation** In the previous section we demonstrated how using a fixed set of \(\gamma, \lambda\) tailored to an intuitive set of progressively large horizons, we could yield performance gains in a number of environments over the single estimator case. However, a performance drop was seen in the case of Zaxxon and WizardOfWor. Due to our bias-variance trade-off in bootstrapping from smaller delta estimators, a curriculum based on smaller horizons may effectively slow learning in some cases. However, the benefit of separating value functions in a flexible way, as we propose here, is that they can be tuned. In Figure 3 (with full results in the Supplemental), we show how different \(\gamma\) values can be used to improve asymptotic performance to match the baseline. By increasing the lowest effective horizon (\(\gamma_0\)) of \(W_0\), we bias the algorithm less toward myopic settings and increase the rate of learning comparable to the baselines. Further tuning of the number of components and their parameters (\(\gamma_z, \lambda_z\), learning rate, etc.) may further improve performance. We expect TD(\(\Delta\)) using our default sequence of \(\gamma_z\) values, without tuning, to particularly help in cases where starting with a small-horizon curriculum and building up is an effective strategy which is reflected in denser reward games such as exemplified in Figure 2.

**7. Discussion**

In this work we explore temporal decomposition of the value function. More concretely, we proposed a novel way for decomposing value estimators via a Bellman update based on the difference between two value estimators with different discount factors. This has convenient theoretical and practical properties which help improve performance in certain settings. These properties have additional benefits: they allow for a natural way to distribute and parallelize training, easy inspection of performance at different discount factors, and the possibility of lifelong learning by adding or removing components. Moreover, we have also highlighted the limitations of this method (introduced bias toward myopic returns) when using the simple parameter settings we propose. However, these limitations can be overcome with the additional ability to tune parameters at different timescales. We briefly discuss these benefits of TD(\(\Delta\)) here.

**Scalability** While we have not pursued it experimentally here, another benefit of separating value functions in this way is that this reflects a natural way of distributing updates across systems for large scale problems. In fact, prior work has sought different ways to scale RL algorithms through partitioning methods (though typically through other means like dividing the state space) (Wingate, 2004; Wingate & Seppi, 2004). Our work provides another such method for scaling RL systems in a different way. A TD(\(\Delta\)) update can be spread across many machines, such that each \(W_z\) is updated separately (as long as weights are synced across machines after a parallel update).

**Additional tuning ability** Many of the performance improvements seen here come not necessarily from the decomposition method itself, but from the ability to set certain parameters differently for each component. The fine-grained nature of the decomposition of the value function allows for further improvement by tuning the number of delta estimators and the \(\gamma_z\) values which correlate with them. In the future, a meta-gradient method as Xu et al. (2018) proposed could be used to automatically scale delta estimators to timescales which require more computational complexity. However, the default method for tailoring \(\gamma_z\) and \(k_z\) and \(\lambda_z\) values as described above (doubling effective horizons until the maximum horizon is reached), still yields improvements in most games tested here, without additional tuning.

**Composing delta estimators and interpreting performance** As we mention in Section 2, another benefit of the TD(\(\Delta\)) method is the ability to examine the value function at different time scales after a single pass of learning. That is,
we can compose value functions from $\gamma_0, \ldots, \gamma_Z$ and understand the differences between different timescales. This has implications for real-world uses with similar motivations as Sherstan et al. (2018) describe. Take for example an MDP where the bulk of rewards are in some central region, requiring following a policy $\pi$ for some number of timesteps before reaching the dense reward region. By examining each $W_z$ component as we do in Figure 2, a practitioner could understand how far into a trajectory $\pi$ must be followed before the dense reward region is reached. This adds some layer of interpretability to the value function which is missing in the single estimator case. Similarly, this may have the benefit in determining an optimal stopping point for the policy. In production system where there is a cost to running a policy (time, money, or energy resources), yet the policy can be run indefinitely, a practitioner may use $W_z$ components to determine if the discounted return at a larger effective horizon is worth the cost.

**Conclusion** We believe that TD($\Delta$) is a valuable drop-in addition to any TD-based training methods that can be applied to a number of existing model-free RL algorithms. We especially highlight the value of this method for performance tuning. We show that a simple sequence of $\gamma_z$ values based on doubling horizon values can yield performance gains especially in dense settings, but this performance can be enhanced further with tuning. As the complexity of modeling and training long-horizon problems increases, TD($\Delta$) may be another tool for scaling and honing production systems for optimal performance.

A. Reproducibility Checklist

We follow the reproducibility checklist (Pineau, 2018) and point to relevant sections explaining them here.

For all algorithms presented, check if you include:

- **A clear description of the algorithm, see main paper and included codebase.** We simply change the TD update as in the main paper. In the case of GAE (as described in the main paper), or TD update matches that of the main paper, per delta estimator.

- **An analysis of the complexity (time, space, sample size) of the algorithm.** See Proofs section in Supplemental Material for bias-variance trade-offs and some rudimentary complexity analysis. Experimentally, we demonstrate similarity or improvements on sample complexity as discussed in main paper. In terms of computation time (for deep experiments) the newly proposed algorithm is almost identical to the baseline due to its parallelizable nature.

- **A link to a downloadable source code, including all dependencies.** See experimental section in Appendix and main paper, the code is included with supplemental as zip file also.

For any theoretical claim, check if you include:

- **A statement of the result.** See supplemental Proof section.

- **A clear explanation of any assumptions.** See supplemental Proof section.

- **A complete proof of the claim.** See supplemental Proof section.

For all figures and tables that present empirical results, check if you include:

- **A complete description of the data collection process, including sample size.** We use standard benchmarks provided in OpenAI Gym (Brockman et al., 2016; Bellemare et al., 2016).

- **A link to downloadable version of the dataset or simulation environment.** See: https://github.com/openai/gym for OpenAI Gym benchmarks and for Ring MDP see included code in experimental section.

- **An explanation of how samples were allocated for training / validation / testing.** We do not use a split because we are examining the optimization performance. Atari environments we use are deterministic, so we run 10 random seeds where the randomness stems from the initialization of the neural networks and policy sampling. As described in Henderson et al. (2018b); Colas et al. (2018) we perform statistical analysis on this seed distribution to determine the range of performance expected of an algorithm for a deterministic environment as compared to the single estimator case. We also run on a hold out set of random starts (we use 1-30 no-ops at the start of training as in Mnih et al. (2013) and show those results in the Supplemental Material).

- **An explanation of any data that were excluded.** We exclude the other Atari games because of time constraints and because we hypothesize that our method will help in dense and complex games as defined in Bellemare et al. (2016).

- **The range of hyper-parameters considered, method to select the best hyper-parameter configuration, and specification of all hyper-parameters used to generate results.** For parity with the baseline, we use similar hyperparameters in the deep learning case as recommended in Schulman et al. (2017); Kostrikov (2018) (described in the experimental section of the Supplemental). In the tabular case we run a grid. For choosing $\gamma_2$ values for our own method we use a schedule as described in the main paper for simplicity and demonstrate how performance can be improved by tuning these values.

- **The exact number of evaluation runs.** 10 seeds for Atari experiments, 3000 episodes per random seed for 200 random seeds for tabular.

- **A description of how experiments were run.** See Experiments section in Supplemental.
The proof is by induction. We first need to show that the base case holds - at time-step $t$ we assume that the statement holds i.e $\sum_{z=0}^Z \theta_{t+1}^W = \theta_{t+1}^V$ and let’s show that it holds at next time-step $t+1$.

\[
\sum_{z=0}^Z \theta_{t+1}^W = \sum_{z=0}^Z \left( \theta_t^W + \alpha_t \left( G_t^W z - \hat{V}_{t}(s_t) \right) \phi(s_t) \right) = \theta_t^V + \sum_{z=0}^Z \alpha_t \left( \sum_{k=t}^\infty (\lambda_t \gamma_t)^{k-t} \delta_k^V \right) \phi(s_t) \quad \text{by induction assumption (22)}
\]

\[
= \theta_t^V + \alpha \sum_{k=t}^\infty (\lambda t \gamma t)^{k-t} \left( \sum_{z=0}^Z \delta_k^V \right) \phi(s_t) \quad \text{thanks to } \alpha_t = \alpha_t, \lambda_t \gamma_t = \lambda t, \forall z \quad (23)
\]

To prove that $\sum_{z=0}^Z \theta_{t+1}^W = \theta_{t+1}^V$, we need to prove that term $(*) = \sum_{z=0}^Z \delta_k^W$ is equal to the standard TD error $\delta_k^V$.

\[
\sum_{z=0}^Z \delta_k^W = r_k + \gamma_0 \hat{V}_{t}(s_{k+1}) - \hat{V}_{t}(s_k) + \sum_{z=1}^{Z} \left( (\gamma_t - \gamma_{t-1}) \sum_{z=0}^{z-1} (\theta_t^W u, \phi(s_{k+1})) + \gamma_t (\theta_t^W u, \phi(s_{k+1})) - (\theta_t^W u, \phi(s_{k})) \right)
\]

\[
= r_k + \gamma_0 \hat{V}_{t}(s_{k+1}) + \sum_{z=1}^{Z} \left( \gamma_t \sum_{u=0}^{z} \theta_t^W u - \gamma_{t-1} \sum_{u=0}^{z-1} \theta_t^W u \right) \phi(s_{k+1}) - \gamma_0 (\theta_t^W u, \phi(s_{k+1})) - (\theta_t^W u, \phi(s_{k}))
\]

\[
= r_k + \gamma_0 \hat{V}_{t}(s_{k+1}) + \gamma_z (\sum_{z=0}^{Z} \delta_k^W u, \phi(s_{k+1})) - \gamma_0 (\theta_t^W u, \phi(s_{t+1})) - \hat{V}_t(s_k)
\]

\[
= r_k + \gamma_0 \hat{V}_{t}(s_{k+1}) - \gamma \hat{V}_t(s_{k+1}) - \gamma_0 \hat{V}_{t}(s_{k+1}) - \hat{V}_t(s_k)
\]

\[
= r_k + \gamma \hat{V}_t(s_{t+1}) - \hat{V}_t(s_k) = \delta_k^\gamma \quad (28)
\]

### B.2. Proof that $\lambda$ can be $> 1$ as long as $\gamma \lambda < 1$ and $\lambda \leq 2$: theorem 2

The Bellman operator is defined as follows:

\[
T^\pi = r^\pi + \gamma P^\pi
\]
where \( r^\pi \) and \( P^\pi \) are respectively the expected reward function and the transition probability operator induced by the policy \( \pi \). The TD(\( \lambda \)) operator is defined as a geometric weighted sum of \( T^\pi \), as follows:

\[
T^\pi_\lambda = (1 - \lambda) \sum_{k=0}^{\infty} \lambda^k (T^\pi)^{k+1}
\]  

(30)

One could conclude that we need \( \lambda \in [0, 1] \) so that the above sum is finite. An equivalent definition of \( T^\pi_\lambda \) is as follows: for all function \( W \)

\[
T^\pi_\lambda W = W + (I - \lambda \gamma P^\pi)^{-1} (T^\pi W - W).
\]  

(31)

The latter formula is well defined if \( 0 \leq \lambda \gamma < 1 \) to guarantee that the spectral norm of the operator \( \lambda \gamma P^\pi \) is smaller that one and hence \( I - \lambda \gamma P^\pi \) is invertible. However, by considering values of \( \lambda \) greater than one, we lose the equivalence between equations 30 and 31. This is not an issue since in practice we use TD error for training which correspond in expectation to the definition of \( T^\pi_\lambda \) given in 31.

Now, let’s study the contraction property of the operator \( T^\pi_\lambda \). First, 31 can be rewritten as :

\[
T^\pi_\lambda = (I - \lambda \gamma P^\pi)^{-1} (T^\pi W - \lambda \gamma P^\pi W).
\]  

(32)

For any functions \( W_1 \) and \( W_2 \), we have:

\[
T^\pi_\lambda W_1 - T^\pi_\lambda W_2 = (I - \lambda \gamma P^\pi)^{-1} (T^\pi W_1 - T^\pi W_2 - \lambda \gamma P^\pi (W_1 - W_2))
\]

\[
= (I - \lambda \gamma P^\pi)^{-1} (\lambda P^\pi (W_1 - W_2) - \lambda \gamma P^\pi (W_1 - W_2))
\]

\[
= (I - \lambda \gamma P^\pi)^{-1} (\gamma (1 - \lambda) P^\pi (W_1 - W_2))
\]  

(33)

We obtain then:

\[
||T^\pi_\lambda W_1 - T^\pi_\lambda W_2|| \leq \frac{\gamma |1 - \lambda|}{1 - \lambda \gamma} ||W_1 - W_2||
\]  

(34)

Therefore, \( T^\pi_\lambda \) is a contraction if \( 0 \leq \gamma \lambda < 1 \) and \( 0 \leq \lambda < 2 \).

**B.3. Expanded Bias-variance comparison proof: theorem 3**

Hoeffding inequality guarantees for a variable that is bounded between \([-1, +1]\), that

\[
P\left( \left| \frac{1}{n} \sum_{j=1}^{n} r^{(j)}_i - \mathbb{E}[r_i] \right| \geq \epsilon \right) \leq 2 \exp \left( \frac{-2n^2\epsilon^2}{n^2} \right)
\]  

(35)

If we assume \( n \) and the probability of exceeding an \( \epsilon \) value is fixed to be no more than \( \delta \), we can solve for the resulting value of \( \epsilon \):

\[
2 \exp \left( \frac{-n^2\epsilon^2}{2n} \right) = \delta \implies -\frac{n\epsilon^2}{2} = \log(\delta/2) \implies \epsilon = \sqrt{\frac{2\log(2/\delta)}{n}}.
\]  

(36)

So by Hoeffding, if we have \( n \) samples, with probability at least \( 1 - \delta \),

\[
\left| \frac{1}{n} \sum_{j} r^{(j)}_i - \mathbb{E}[r_i] \right| \leq \epsilon = \sqrt{\frac{2\log(2/\delta)}{n}}.
\]  

(37)

Since we want each of the \( k \) \( \mathbb{E}[r_i] \) reward terms to all be estimated up to \( \epsilon \) accuracy with high probability, we can use a union bound to ensure that the probability that we fail to estimate any of these \( k \) expected reward terms is \( \delta \) by requiring that the probability we fail to estimate any of them is at most \( \delta/k \). Substituting this into the above equation for \( \epsilon \), we obtain that with probability at least \( 1 - \delta \), each of the \( \mathbb{E}[r_i] \) terms are estimated to within \( \epsilon = \sqrt{\frac{2\log \frac{2\delta}{k}}{n}} \) accuracy.

This is a slightly different expression than Kearns & Singh (2000) obtain in terms of constants, it is unclear which inequality was used to come to their method as their proof was omitted.
We can now assume that all $E[r_i]$ terms are estimated to at least $\epsilon$ accuracy. Substituting this back into the definition of the $k$-step TD update we get

$$
\hat{V}^\pi_{t+1}(s) - V^\pi(s) = \frac{1}{n} \sum_{j=1}^{n} \left( r^{(j)}_0 + \gamma r^{(j)}_1 + \ldots + \gamma^{k-1} r^{(j)}_{k-1} + \gamma^{k} V^\pi_i(s^{(j)}_k) \right) - V^\pi(s)
$$

where in the second line we re-expressed the value in terms of a sum of $k$ rewards. We now upper bounded the difference from $E[r_i]$ by $\epsilon$ to get

$$
\hat{V}^\pi_{t+1}(s) - V^\pi(s) \leq \frac{k-1}{n} \epsilon + \gamma^{k} \left( \frac{1}{n} \sum_{i=1}^{n} V^\pi_i(s^{(j)}_k) - E[V^\pi(s_k)] \right)
$$

and then the second term is bounded by $\Delta^\gamma_{t-1}$ by assumption. Hence, we obtain:

$$
\Delta^\gamma_t \leq \epsilon \left( \frac{1 - \gamma}{1 - \gamma} \right) + \gamma^{k} \Delta^\gamma_{t-1}
$$

**B.4. Proving error bound for phased TD(\Delta): theorem 4**

Phased TD($\Delta$) update rules for $z \geq 1$:

$$
\hat{W}_z(s) = \frac{1}{n} \sum_{j=1}^{n} \left( \sum_{i=1}^{k-1} (\gamma^i_z - \gamma^i_{z-1}) r^{(j)}_i + (\gamma^{k_z}_z - \gamma^{k_{z-1}}_z) \hat{V}^{\gamma}_{z-1}(s^{(j)}_k) + \gamma^{k_z}_z \hat{W}_z(s^{(j)}_k) \right)
$$

We know that according to the multi-step update rule 8 for $z \geq 1$:

$$
W_z(s) = E \left[ \sum_{i=1}^{k_z} (\gamma^i_z - \gamma^i_{z-1}) r_i + (\gamma^{k_z}_z - \gamma^{k_{z-1}}_z) V^{\gamma}_{z-1}(s_k) + \gamma^{k_z}_z W_z(s_k) \right]
$$

Then, subtracting the two expressions gives for $z \geq 1$:

$$
\hat{W}_z(s) - W_z(s) = \frac{k_z - 1}{n} \left( \sum_{i=1}^{n} r^{(j)}_i - E[r_i] \right) + (\gamma^{k_z}_z - \gamma^{k_{z-1}}_z) \left( \sum_{u=0}^{z-1} W_u(s^{(j)}_k) - E[W_z(s_k)] \right)
$$

Assume that $k_0 \leq k_1 \leq \ldots \leq k_Z = k$, the $W$ estimates share at most $k_Z = k$ reward terms $\frac{1}{n} \sum_{j=1}^{n} r^{(j)}_i$. Using Hoeffding inequality and union bound, we obtain that with probability $1 - \delta$, each $k$ empirical average reward $\frac{1}{n} \sum_{j=1}^{n} r^{(j)}_i$ deviates from the true expected reward $E[r_i]$ by at most $\epsilon = \sqrt{\frac{2 \log(2kZ/\delta)}{n}}$. Hence, with probability $1 - \delta, \forall z \geq 1$, we have:

$$
\Delta^W_z \leq \epsilon \sum_{i=1}^{k_z} (\gamma^i_z - \gamma^i_{z-1}) + (\gamma^{k_z}_z - \gamma^{k_{z-1}}_z) \sum_{u=0}^{z-1} \Delta^W_{u} + \gamma^{k_z}_z \Delta^W_{z-1}
$$

and

$$
\Delta^W_z \leq \epsilon \left( \frac{1 - \gamma^{k_z}_z}{1 - \gamma_z} \right) + (\gamma^{k_z}_z - \gamma^{k_{z-1}}_z) \sum_{u=0}^{z-1} \Delta^W_{u} + \gamma^{k_z}_z \Delta^W_{z-1}
$$
and

\[ \Delta W_0 \leq \frac{1 - \gamma k_0}{1 - \gamma_0} + \gamma_0 k_0 \Delta W_0 \]  

(49)

Summing the two previous inequalities gives:

\[ \sum_{z=0}^{Z} \Delta W_z \leq \frac{1 - \gamma k_z}{1 - \gamma_z} + \epsilon \sum_{z=0}^{Z} \frac{1 - \gamma k_z}{1 - \gamma_z} - \frac{1 - \gamma k_{z-1}}{1 - \gamma_{z-1}} \]  

(50)

\[ \sum_{z=0}^{Z} \Delta W_z \leq \frac{1 - \gamma k_z}{1 - \gamma_z} + \epsilon \sum_{z=0}^{Z} \left( \frac{1 - \gamma k_z}{1 - \gamma_z} - \frac{1 - \gamma k_{z-1}}{1 - \gamma_{z-1}} \right) + \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \sum_{u=0}^{z-1} \Delta W_u + \gamma_{k_z} \Delta W_z \]  

(51)

Let’s focus now further on the bias term (**):

\[ \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \sum_{u=0}^{z-1} \Delta W_u + \gamma_{k_z} \Delta W_z = \sum_{u=0}^{Z-1} \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \Delta W_{u-1} + \sum_{z=1}^{Z} \gamma_{k_z} \Delta W_z \]  

(52)

\[ \sum_{u=0}^{Z-1} \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \Delta W_{u-1} + \sum_{z=1}^{Z} \gamma_{k_z} \Delta W_z = \sum_{u=0}^{Z-1} \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \Delta W_{u-1} + \gamma_{k_z} \sum_{z=0}^{Z} \Delta W_z - \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \Delta W_{u-1} \]  

(53)

\[ \sum_{u=0}^{Z-1} \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \Delta W_{u-1} + \gamma_{k_z} \sum_{z=0}^{Z} \Delta W_z - \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \Delta W_{u-1} = \sum_{u=0}^{Z-1} \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \Delta W_{u-1} + \gamma_{k_z} \sum_{z=0}^{Z} \Delta W_z \]  

(54)

\[ \sum_{u=0}^{Z-1} \sum_{z=0}^{Z} (\gamma_{k_z} - \gamma_{k_{z-1}}) \Delta W_{u-1} + \gamma_{k_z} \sum_{z=0}^{Z} \Delta W_z \]  

(55)

Finally, we obtain:

\[ \sum_{z=0}^{Z} \Delta W_z \leq \frac{1 - \gamma k_z}{1 - \gamma_z} + \epsilon \sum_{z=0}^{Z-1} \gamma_{k_z} \Delta W_{u-1} + \gamma_{k_z} \sum_{z=0}^{Z} \Delta W_z \]  

(58)

C. Experiments

C.1. Additional Details on Experimental Setup

All code can be found in: https://github.com/facebookresearch/td-delta.

C.1.1. Tabular

We use value iteration to find the optimal value function. We run an open-source version of value iteration from https://github.com/Breakend/ValuePolicyIterationVariations based on the algorithm details in Bellman (1957); Sutton & Barto (1998). All episodes are stopped at 500 timesteps and training is run for 100 episodes. We run 250 experiments per setting with different random seeds affecting the transition dynamics (random seeds 0 – 249 used).
We use the 5-state ring MDP in Kearns & Singh (2000). In each state there’s a transition probability of .95 to the next state and .05 of staying in the current state. Two adjacent states in the environment have a +1 and -1 reward respectively. Example in Figure C.1.1.

Results

| Algorithm | Zaxxon | WizardOfWor | MsPacman | Hero | Frostbite | BankHeist | Amidar | Alien |
|-----------|--------|-------------|----------|------|-----------|-----------|--------|-------|
| PPO-TD(Δ, GAE) | 451 ± 252 | 2060 ± 140 | 13926 ± 576 | 2336 ± 127 | 29224 ± 742 | 267 ± 3 | 1176 ± 25 | 740 ± 31 |
| PPO-TD(Δ, GAE)-λ | 3227 ± 797 | 2402 ± 154 | 13328 ± 409 | 2224 ± 75 | 28913 ± 1036 | 267 ± 10 | 1163 ± 12 | 668 ± 60 |
| PPO+ | 6890 ± 269 | 2821 ± 351 | 10521 ± 622 | 1907 ± 94 | 23670 ± 96 | 269 ± 2 | 1185 ± 10 | 605 ± 32 |

Frequencies of random policies vs learned policies can be seen in Figure 5. In the case of Frostbite, we achieve equal performance in all algorithm cases. We suspect this to be a limitation of on-policy learning with PPO and achieves similar results to the original codebase from Schulman et al. (2017). Using more advanced exploration and off-policy learning may change the local minimum which seems to be found here.

For tabular results please see Figures 6, 7, 8, 9, 10, 11, and 12.

C.1.2. Atari

We use the NoFrameSkip-v4 version of all environments.

Hyperparameters

We use mostly the same hyperparameters as suggested by Schulman et al. (2017); Kostrikov (2018). We use seeds [125125, 513, 90135, 81212, 3523401, 15709, 17, 0, 8412, 1153780] generated randomly. For the TD(Δ) version of the algorithm we set γz such that γz = γ and then we set γz−1 = 1/((1−γz)) while γz > .5. The rest of the hyperparameter

| Algorithm | Zaxxon | WizardOfWor | MsPacman | Hero | Frostbite | BankHeist | Amidar | Alien |
|-----------|--------|-------------|----------|------|-----------|-----------|--------|-------|
| PPO-TD(Δ, GAE) | 199 ± 63 | 1653 ± 61 | 7812 ± 254 | 1729 ± 30 | 17805 ± 263 | 276 ± 3 | 732 ± 25 | 432 ± 18 |
| PPO-TD(Δ, GAE)-λ | 1259 ± 286 | 1747 ± 47 | 8078 ± 201 | 1704 ± 35 | 16846 ± 289 | 276 ± 7 | 717 ± 38 | 444 ± 20 |

| PPO | 3776 ± 284 | 2247 ± 70 | 5763 ± 217 | 1275 ± 35 | 13146 ± 370 | 267 ± 2 | 928 ± 13 | 395 ± 15 |

Table 3. Average Atari performance (across all training episodes) with the mean and standard error across 10 seeds. See Table 1 for more details.
Figure 5. Frequency of rewards per 100 time-steps averaged over 10000 time-steps. Notice how the task ‘Zaxxon’ has a much lower frequency (approximately 2 orders of magnitude) than the largest frequency task (Ms Pacman).

Figure 6. $\gamma = .75$ and different k values at different learning rates.
Figure 7. $\gamma = .875$ and different $k$ values at different learning rates.

Figure 8. $\gamma = .93750$ and different $k$ values at different learning rates.
Figure 9. $\gamma = .96875$ and different k values at different learning rates.

Figure 10. $\gamma = .98475$ and different k values at different learning rates.
Figure 11. $\gamma = .992$ and different $k$ values at different learning rates.

Figure 12. $\gamma = .996$ and different $k$ values at different learning rates.
settings can be found in Table 4.

| Hyperparameter          | Value                  |
|-------------------------|------------------------|
| Learning Rate           | $2.5 \times 10^{-4}$   |
| Clipping parameter      | 0.1                    |
| VF coeff                | 1                      |
| Number of actors        | 8                      |
| Horizon(T)              | 128                    |
| Number of Epochs        | 4                      |
| Entropy Coeff.          | 0.01                   |
| Discount $(\gamma, \gamma)$ | .99                   |

Table 4. Hyperparameters common to both PPO baseline and PPO with TD($\Delta$, GAE).

Results

Figure 13. Performance of different TD($\Delta$) variations and baselines on all 9 Hard games with dense rewards. ppoDelta refers to setting $\gamma_s \lambda = \gamma \lambda \forall z$. ppoDeltaCappedLambda uses the same $\gamma$s but caps all $A$s at 1.0 - introducing bias that helps in most cases. Standard error across random seeds is represented in shaded regions.
Figure 14. Performance of different TD(Δ) variations and baselines on all 9 Hard games with dense rewards. ppoDelta refers to setting $\gamma_z \lambda_z = \gamma \lambda \forall z$. ppoDelta3 and ppoDelta12 only use two value functions - the first having a corresponding horizon of 3 and 12 respectively and the second 100. We see that bias is induced both from the number of estimators as well as the shortest horizon. Standard error across random seeds is represented in shaded regions.
Figure 15. Each $W_z$ estimator for various games versus the reward of a policy on a single rollout trajectory.
Figure 16. Each $W_e$ estimator for various games versus the reward of a policy on a single rollout trajectory.
Figure 17. Each $W_e$ estimator for various games versus the reward of a policy on a single rollout trajectory.
