Abstract: From December 2011 to May 2014, about 5 fb$^{-1}$ of data were taken with the BESIII detector at center-of-mass energies between 3.810 GeV and 4.600 GeV to study the charmonium-like states and higher excited charmonium states. The time-integrated luminosity of the collected data sample is measured to a precision of 1% by analyzing events produced by the large-angle Bhabha scattering process.

Key words: precision measurement, luminosity, Bhabha scattering, charmonium

1 Introduction

As a τ-charm factory, the BESIII experiment has collected the world’s largest sample of e⁺e⁻ collision data at center-of-mass (CM) energies between 3.810 GeV and 4.600 GeV. In this energy region, the charmonium-like states and higher excited charmonium states are produced copiously, which makes comprehensive studies possible.

The charmonium-like states discovered in recent years have drawn great attention from both theorists and experimentalists for their exotic properties, as reviewed e.g. in Ref. [1]. Being well above the open charm threshold, the strong coupling of these states to hidden charm processes makes their interpretation as conventional charmonium states very difficult. On the other hand, the theory of the strong interaction, Quantum Chromodynamics (QCD), does not prohibit the existence of exotic states beyond the quark model, e.g. molecular states, tetraquark states, hybrid states, etc. Either the verification or the exclusion of the existence of such states will help to evaluate the quark model and better understand QCD. Even though some states have been identified as higher excited charmonium states, such as the ψ(4040), ψ(4160), and ψ(4415), their large widths and interference with each other make their precise study complicated. In addition, the relationship between the charmonium-like states and higher excited charmonium states is still not clear. Precise knowledge of the time-integrated luminosity is essential for quantitative analysis of these states.

In this paper, we present a measurement of the integrated luminosity based on analysis of the Bhabha scattering process e⁺e⁻ → (γ)e⁺e⁻. A similar method has been used in the luminosity measurement of ψ(3770) data at BESIII [2]. The process has a simple and clean signature and a large production cross section, which allows for a small systematic and a negligible statistical uncertainty. A cross check of the result is performed by analyzing the di-gamma process e⁺e⁻ → γγ.

2 The detector

BESIII is a general purpose detector which covers 93% of the solid angle and operates at the e⁺e⁻ collider BEPCII. A detailed description of the facilities is given in Ref. [3]. The detector consists of four main components: (a) A small-cell, helium-based main drift chamber (MDC) with 43 layers provides an average single-hit resolution of 135 μm, and a momentum resolution of 0.35% for charged tracks at 1 GeV/c in a 1 T magnetic field; (b) An electro-magnetic calorimeter (EMC), consisting of 6240 CsI(Tl) crystals in a cylindrical structure (barrel and two endcaps). The energy resolution for 1.0 GeV photons is 2.5% (5%) in the barrel (endcaps), while the position resolution is 6 mm (9 mm) in the barrel (endcaps); (c) A time-of-flight system (TOF), constructed of 5 cm thick plastic scintillators, arranged in 88 detectors of 2.4 m length in two layers in the barrel and 96 fan-shaped detectors in the endcaps. The barrel (endcap) time resolution of 80 ps (110 ps) provides 2σ K/π separation for momenta up to about 1.0 GeV/c; (d) A muon counter (MUC), consisting of nine layers of resistive plate chambers in the barrel and eight layers for each endcap. It is incorporated in the iron return yoke of the superconducting magnet. Its position resolution is about 2 cm. A GEANT4 [4, 5] based detector simulation package has been developed to model the detector response. Due to the crossing angle of the beams at the interaction point, the e⁺e⁻ CM system is slightly boosted with respect to the laboratory frame.

3 Data sample and Monte Carlo simulation

Twenty-one data samples have been taken at CM energies between 3.810 GeV and 4.600 GeV. Six of the data sets exceed the others in accumulated statistics by an order of magnitude. These samples were taken on the peaks of charmonium-like states, like the Y(4260), Y(4360), and Y(4630), or higher excited charmonium states, like ψ(4040), and ψ(4415), in order to study these resonances and their decays in great detail. The data samples taken at the other CM energies serve as scan points to study the behavior of the cross section around these resonances. All individual data samples are listed in Table 1.

At each energy point, one million Bhabha events were generated using the BABAYAGA3.5 [6] generator with the options presented in Table 2. For the BABAYAGA3.5 generator, the uncertainty in calculating the cross section is 0.5%, which meets the demand of the total uncertainty of luminosity measurement. The kinematic distributions of the final state particles from the BABAYAGA3.5 generator are consistent with those from data. In the simulation, the scattering angles of the final state particles were limited to a range from 20° to 160°, which slightly exceeds the angular acceptance of the detector, in order to save on computing resources. An energy threshold of 0.04 GeV was applied to the final state particles. The acollinearity of the events has not been constrained. Finally, the generation was taking into account the running of the electromagnetic coupling constant and final state radiation (FSR).

To study the background and optimize the event selection criteria, an inclusive Monte Carlo (MC) sample corresponding to a luminosity of 500 pb⁻¹ at CM energy of 4.260 GeV was generated, in which the Quantum Electrodynamics (QED) processes e⁺e⁻ → e⁺e⁻,
\[ e^+e^- \rightarrow \mu^+\mu^- \text{ and } e^+e^- \rightarrow \gamma\gamma, \] the continuum production of hadrons, and the initial state radiation (ISR) to \( J/\psi \) and \( \psi(3686) \) resonance process were included. The babayaga3.5 generator was used to simulate the relevant QED processes. Other processes, such as the decays of the \( J/\psi \), were generated with specialized models that have been packaged and customized for the BESIII Offline Software System (BOSS) (see [7] for an overview).

Table 1. Center-of-mass energy, luminosity obtained from the nominal measurement \( (L) \), cross check results \( (L_{\text{ck}}) \), and relative differences between the two results. The uncertainties are statistical only. Superscripts indicate separate samples acquired at the same CM energy.

| FSR switch    | 1     |

4 Event selection and results

Signal candidates are required to have exactly two oppositely charged tracks. The tracks must originate from a cylindrical volume, centered around the interaction point, which is defined by a radius of 1 cm perpendicular to the beam axis and a length of ±10 cm along the beam axis. In addition, the charged tracks are required to be within \(|\cos \theta| < 0.8\), where \( \theta \) is the polar angle, measured by the MDC. Without applying further particle identification, the tracks are assigned as electron and positron depending on their charge. The deposited energies of electron and positron in EMC must be larger than \( \sqrt{s}/4.26 \times 1.55 \) (GeV) to remove the di-muon background, where \( \sqrt{s} \) is the CM energy in GeV; the momenta of electron and positron are required to be larger than \( \sqrt{s}/4.26 \times 2 \) (GeV/c), to suppress background events from lighter vector resonances produced in the ISR process, such as \( J/\psi, \psi(3686) \) and other resonances, decaying into \( e^+e^- \) pairs. For the data sample with a CM energy of 3.810 or 3.910 GeV, the effect of the remaining \( \psi(3686) \) events is studied by applying a 20% larger momentum requirement, and is found to be negligible. The requirements on the deposited energies and momenta are not optimized in detail, as the number of the signal events in such an analysis is large enough. All the variables mentioned above are determined in the initial \( e^+e^- \) CM frame. The ratio of the number of remaining background events to the number of signal events, estimated from the inclusive MC sample, is found to be less than \( 2 \times 10^{-4} \), which is negligible. Thus all the selected events are taken as Bhabha events.

Figure 1 shows the comparisons between data and MC simulation for the kinematic variables of the leptons by taking data at the CM energy of 4.260 GeV as an example. Reasonable agreement is observed in the angular and momentum distributions. The striking difference between data and simulation found in the distributions of energies deposited by the leptons in the EMC emerges from imperfections in the simulation of the energy response of individual detector channels. At the CM energies analyzed in this work, a single shower in the calorimeter can be so energetic that the deposited energy per crystal exceeds the dynamic range of the analog-to-digital converter (ADC), causing individual ADC channels to saturate. In the analysis presented here, the very loose requirements on the energy deposits will not cause any bias, since they have been applied in regions of reasonable agreement between data and simulation. Relevant deviations between data and MC are considered as contributions to the systematic uncertainties.

The integrated luminosity is calculated with

\[
L = \frac{N_{\text{obs}}}{\sigma_{\text{Bhabha}} \epsilon},
\]

where \( N_{\text{obs}} \) is the number of observed Bhabha events, \( \sigma_{\text{Bhabha}} \) is the cross section of the Bhabha process, and \( \epsilon \) is the efficiency determined by analyzing the signal MC sample. The cross sections are calculated with the babayaga3.5 generator using the parameters listed in Table 2 and decrease with increasing energies. The efficiencies are almost independent of the CM energy, as intended by the choice of relative conditions on lepton momenta and deposited energies. The luminosity results
calculated with Eq. (1) are listed in Table 1. The statistical accuracy of the resulting integrated luminosity is better than 0.1% at all energy points.

5 Systematic uncertainty

The following sources of systematic uncertainties are considered: the uncertainty of the tracking efficiency, the uncertainty related to the requirements on the kinematic variables, the statistical uncertainty of the MC sample, the uncertainty of the beam energy measurement, the uncertainty of the trigger efficiency, and the systematic uncertainty of the event generator.

To estimate the systematic uncertainty related to the tracking efficiency, the Bhabha event sample is selected using information from the EMC only, without using the tracking information in the MDC. The selection criteria are: at least two clusters in the EMC for each candidate, and the two most energetic clusters are assumed to originate from the $e^+e^-$ pair; the deposited energies of the two clusters are required to be larger than $\sqrt{s}/4.26 \times 1.8$ (GeV).

At CM energies above 4.420 GeV, the requirement is changed to $\sqrt{s}/4.26 \times 1.55$ (GeV). This adjustment allows us to avoid additional systematic uncertainties which would be introduced by the deviation of data and simulation in the deposited energy in the EMC, as discussed in Section 4. The polar angle of each cluster is required to be within $|\cos \theta^{\text{EMC}}| < 0.8$, where $\theta^{\text{EMC}}$ is the polar angle measured by the EMC; to remove the background from the di-photon process, $\Delta \phi$ is required to be in the range of $[-40^\circ, -5^\circ]$ or $[5^\circ, 40^\circ]$, where $\Delta \phi = |\phi_1 - \phi_2| - 180^\circ$ and $\phi_{1,2}$ are the azimuthal angles of the clusters in the EMC boosted to the CM frame. The efficiency that the selected Bhabha events pass through the track requirements applied in the nominal analysis is calculated for both data and MC sample, and the difference between them is taken as the systematic uncertainty connected to the tracking efficiency.

The systematic uncertainty in the polar angle acceptance is estimated by changing the requirement from $|\cos \theta| < 0.8$ to $|\cos \theta| < 0.7$. The difference between the resulting and nominal luminosity is taken as the associ-
The systematic uncertainty caused by the requirement on the energy deposited in the EMC is estimated by changing the requirement from $\sqrt{S}$ = 1.55 (GeV) to $\sqrt{S}$ = 1.71 (GeV). The systematic uncertainty caused by the requirement on the momentum is estimated by changing the requirement from $\sqrt{S}$ = 2 (GeV/c) to $\sqrt{S}$ = 2.06 (GeV/c). The ranges are picked as these cause the largest deviations from the nominal luminosity result near the requirements applied.

The statistical uncertainty of the efficiency determined from MC simulations is 0.25%. The CM energy is estimated by changing the requirement from the EMC is calculated taking into account ISR and FSR effects. The difference between the CM energy listed in Table 1 and that measured with the di-muon system is calculated taking into account ISR and FSR effects. The invariant mass of the di-muon system is calculated into taking account ISR and FSR effects. The invariant mass of the di-muon system is calculated taking into account ISR and FSR effects. The difference between the CM energy by 2 MeV in the MC simulation. The trigger efficiency for the Bhabha process is 100% with an uncertainty of less than 0.1% [8]. The theoretical uncertainty is dominated by the systematic uncertainty. A cross check with di-gamma events is performed and the results are consistent with each other. The result presented here is essential for future measurements of cross sections with these data, and has already been used in the discovery of charged charmonium-like states [9–12].

The BESIII collaboration would like to thank the staff of BEPCII and the IHEP computing center for their dedicated support.
