We show that four-dimensional $\mathcal{N} = 2$ supersymmetric $SU(N)$ gauge theory for $N > 2$ necessarily contains vacua with mutually non-local massless dyons, using only analyticity of the effective action and the weak coupling limit of the moduli space of vacua. A specific example is the $\mathbb{Z}_3$ point in the exact solution for $SU(3)$, and we study its effective Lagrangian. We propose that the low-energy theory at this point is an $\mathcal{N} = 2$ superconformal $U(1)$ gauge theory containing both electrically and magnetically charged massless hypermultiplets.
1. Introduction

Over the last year and a half, the work of Seiberg and collaborators [1] has led to a remarkable variety of exact results for four-dimensional supersymmetric gauge theories. Many old models for physical phenomena, such as the monopole condensation model of confinement, have explicit realizations in these theories. Even more exciting are the new phenomena which have been discovered, such as duality between $\mathcal{N} = 1$ gauge theories, novel interacting fixed points, and chiral symmetry breaking by monopole condensation.

An exact low-energy effective Lagrangian for pure $\mathcal{N} = 2$ supersymmetric $SU(2)$ gauge theory was proposed by Seiberg and Witten [2], and generalized in [3,4] to $SU(N)$ gauge groups. $\mathcal{N} = 2$ supersymmetric gauge theory contains a complex adjoint (matrix) scalar $\phi$, whose expectation value parameterizes physically distinct vacua. We refer to the space of vacua as moduli space, and gauge-invariant coordinates parametrizing it (moduli) are the $N - 1$ quantities $\text{Tr}\phi^n$.

Classically, $\phi$ can take any vev satisfying $[\phi, \phi^+] = 0$ and so it can be diagonalized; let its eigenvalues be $\phi_i$. For distinct $\phi_i$ this vev breaks $SU(N)$ to the Abelian group $U(1)^{N-1}$. The classical analysis is justified for $\phi_i - \phi_j$ large compared to the scale $\Lambda$ where the gauge coupling of the unbroken quantum theory would become strong, and the low-energy physics of such vacua is described by weakly coupled $\mathcal{N} = 2$ supersymmetric $U(1)^{N-1}$ gauge theory. The semiclassical treatment also predicts the existence of monopoles and dyons, which form hypermultiplets of $\mathcal{N} = 2$. This analysis breaks down if any non-abelian subgroup remains unbroken at the scale $\Lambda$, which can be arranged by tuning any of the $\phi_i - \phi_j$ to be $O(\Lambda)$.

In the exact (quantum) solution of these theories, the moduli space remains the same, and there is a description of the low-energy physics of each vacuum as a weakly coupled $\mathcal{N} = 2$ supersymmetric $U(1)^{N-1}$ gauge theory, but one not necessarily written in terms of the original gauge fields. The essential feature of the quantum theory is that by tuning a modulus, one can make a monopole or dyon hypermultiplet massless. Each such hypermultiplet will become massless on a submanifold of moduli space of complex codimension one. By a duality transformation to the appropriate ‘magnetic’ variables, the low energy $U(1)^{N-1}$ theory is equivalent to a theory with one massless ‘electron’ hypermultiplet.
The intersection of two or more of these submanifolds results in a submanifold of smaller complex dimension where the massless hypermultiplets are two or more ‘electrons,’ each charged with respect to a different $U(1)$ factor.

As pointed out in \cite{5}, the $SU(N)$ solutions of \cite{3,4} have in addition other vacua where two or more field operators with mutually non-local charges become massless. These fields create the standard ’t Hooft-Polyakov monopoles visible in the semiclassical limit, and dyons produced from them by shifts of the $\theta$ angle \cite{6}.

By mutually non-local charges we mean that

\[ h^{(1)} \cdot q^{(2)} - h^{(2)} \cdot q^{(1)} \neq 0, \tag{1.1} \]

where $h^{(i)}$ and $q^{(i)}$ are the vectors of magnetic and electric charges of the $i$’th dyon with respect to the $N - 1$ $U(1)$ factors. When this product is non-zero, no duality transformation will turn the theory into one with only electrically charged elementary fields; at least one of the elementary fields will have magnetic charge. Thus the Lagrangian must simultaneously contain the standard vector potential coupling locally to electrons, and the dual vector potential coupling locally to elementary monopoles. A manifestly Lorentz invariant Lagrangian of this type is not known, and indeed the construction of any Lagrangian of this type is fairly recent \cite{7}.

Several formulations of the quantum mechanics of a finite number of electrons and monopoles exist, for example in \cite{8,9}. No definite reason was found that its physics could not be sensible and local. A necessary condition, satisfied here, is that the product (1.1) is always integral \cite{8}. The new elements here are that the particles are massless and can be pair produced ad infinitum, so that one needs a field-theoretic description. Indeed, whether there is a ‘particle’ interpretation of the physics is not at all clear, as we will see.

We propose that these vacua of $SU(N)$ supersymmetric gauge theory provide ‘explicit’ local realizations of such theories, thus demonstrating their existence. Besides the difficulties associated with mutually non-local gauge charges, the theories will turn out to be strongly coupled, so the direct definition is not easy to study. $SU(N)$ gauge theory at these special vacua is convenient for this purpose, as it contains only these low energy degrees of freedom together with pure $U(1)$ gauge multiplets. All other degrees of freedom
have mass $O(\Lambda)$ and decouple in the low energy limit.

Since these vacua occur at singularities of complex codimension one submanifolds, they are themselves at least of complex codimension two. Thus the first place one could see them is at isolated points in the two complex dimensional $SU(3)$ moduli space. We focus on this theory because of its simplicity, though when it is easy to do so, we describe the generalization to the $SU(N)$ theories.

Near the singular vacuum, the theory contains an adjustable second scale $m \ll \Lambda$, and the effective Lagrangian strongly motivates the claim that between the scales $\Lambda$ and $m$, the theory is at an RG fixed point. Exactly at the special vacuum, $m \rightarrow 0$ and the low-energy theory is a fixed point, an $\mathcal{N} = 2$ superconformal theory. By taking the limit $\Lambda \rightarrow \infty$, one defines a superconformal theory without the extra degrees of freedom of $SU(N)$ gauge theory. Our $SU(3)$ example produces a $\mathcal{N} = 2 U(1)$ gauge theory coupled to three hypermultiplets, and we propose a definition of the superconformal theory containing only these degrees of freedom.

Another way to single out the special vacuum is to add the superpotential $\text{Tr} \phi^3$ to the gauge theory, which produces an $\mathcal{N} = 1$ theory with discrete ground states, two of which are $\mathcal{N} = 1$ deformations of the $\mathcal{N} = 2$ fixed point theory.

Although we will give strong evidence for our picture of the physics, since we do not have a complete understanding of the field-theoretic description, we also discuss possible alternative interpretations in detail. Of course one possible interpretation would be that we have found evidence that the $SU(N)$ solutions of [3,4] are incorrect. We address this possibility by showing that the existence of vacua with massless dyons with mutually non-local charges follows solely from analyticity and the topology of the embedding of the $SU(2)$ moduli space found in [2], in the weak coupling limit of the $SU(3)$ moduli space. Thus it is assured independent of the details of the solutions of [3,4]. Further confirmation of the solutions can be found in the physically sensible results and interpretation of [3], and by a partially independent derivation, as a limit of the $N_f = 2N_c$ solution found in [10].

A competing interpretation of the fixed point would be as an interacting non-abelian Coulomb phase of the sort found in [11,12]. The obvious test of this possibility is to look for
non-abelian gauge bosons, which by definition must be present in a non-abelian Coulomb phase. Using the solution of [3,4], we will show that they are not.

In section 2 we describe the non-local vacua in the context of a detailed picture of the complete $SU(3)$ moduli space. In section 3 we show that their existence follows from analyticity and the topology of the embedding of the $SU(2)$ moduli space found in [2] in the weak coupling limit of the $SU(3)$ moduli space. In section 4 we compute the effective action near these points, both in the $\mathcal{N} = 2$ theory, and in the $\mathcal{N} = 1$ theory with a renormalizable superpotential. In section 5 we compare physical interpretations of the theory, and conclude that the evidence favors the interpretation as a $U(1)$ theory with mutually non-local charged fields, and furthermore that the theory at intermediate scales is a fixed point theory, an interacting $\mathcal{N} = 2, D = 4$ superconformal field theory. We study its basic properties in section 6. As observed in previous work, loop contributions of particles with $U(1)$ magnetic charges tend to make the electric gauge coupling relevant. We point out that given coexisting particles with mutually non-local charges, there is a novel way to produce fixed points – their contributions to the beta function can cancel. We show that many features of our effective Lagrangian can be explained by this interpretation.

2. Singularities in $SU(3)$ Moduli Space

Gauge-invariant coordinates on the $SU(N)$ moduli space can be taken to be the elementary symmetric polynomials $s_\ell$, $\ell = 2, \ldots, N$, in the eigenvalues of $\langle \phi \rangle$

$$\det(x - \langle \phi \rangle) = \sum_{\ell=0}^{N} (-1)^\ell s_\ell x^{N-\ell}$$

$s_0 = 1$ and $s_1 = 0$ by the $SU(N)$ tracelessness condition. At a generic point in moduli space where $\langle \phi \rangle$ breaks the gauge symmetry to $U(1)^{N-1}$, the low energy effective Lagrangian can be written in terms of the $\mathcal{N} = 2$ $U(1)$ gauge multiplets $(A_i, W_i)$, $i = 1, \ldots, N - 1$, where the $A_i$ are $\mathcal{N} = 1$ chiral superfields and the $W_i$ are $\mathcal{N} = 1$ (chiral) gauge superfields. We denote the scalar component of $A_i$ by $a_i$. The $\mathcal{N} = 2$ effective Lagrangian is determined by an analytic prepotential $\mathcal{F}(A_i)$ and takes the form

$$\mathcal{L}_{\text{eff}} = \text{Im} \frac{1}{4\pi} \left[ \int d^4 \theta \, A^+_D A^+_i + \frac{1}{2} \int d^2 \theta \, \tau^{ij} W_i W_j \right],$$

where $\tau^{ij}$ is the hypermultiplet superpotential.
where the dual chiral fields and the effective couplings are given by

\[ A^i_D \equiv \frac{\partial F}{\partial A_i}, \quad \tau^{ij} \equiv \frac{\partial^2 F}{\partial A_i \partial A_j}. \] (2.3)

Typically, this effective action is good for energies less than \( \Lambda \), the \( SU(N) \) strong-coupling scale, except for regions of size \( \sim \Lambda \) around special submanifolds of moduli space where extra states become massless. As we approach these submanifolds the range of validity of (2.2) shrinks to zero; on these singular submanifolds the effective Lagrangian must be replaced with one which includes the new massless degrees of freedom.

2.1. Charges and Monodromies

The \( U(1)^{N-1} \) effective theory has a lattice of allowed electric and magnetic charges, \( q^i \) and \( h_i \), generated by the fundamental representation weights \( (q^{(l)})^i = \delta^{l,i} \) for the electric charges, and the dual basis \( (h^{(l)})_i = \delta^l_i \) for the magnetic charge lattice. BPS saturated hypermultiplets in these theories have effective Lagrangian

\[
\int d^4 \theta \ M e^{V \cdot q + V_D \cdot h} + \tilde{M} e^{-V \cdot q - V_D \cdot h} + \int d^2 \theta \ \sqrt{2} (A \cdot q + A_D \cdot h) \tilde{M} + \text{h.c.}
\] (2.4)

so have a mass given by [14]

\[ M = \sqrt{2} |a \cdot q + a_D \cdot h|. \] (2.5)

The physics described by the \( U(1)^{N-1} \) effective theory is invariant under an \( Sp(2N-2; \mathbb{Z}) \) group of duality transformations, which acts on the scalar fields and their duals, as well as the electric and magnetic charges of all states. Encircling any singularity in moduli space (submanifold where extra states become massless) produces a non-trivial \( Sp(2N-2; \mathbb{Z}) \) transformation. Thus \( F(A) \) and the scalar fields \( a_i \) of the effective Lagrangian are not single-valued functions on the moduli space.

More explicitly, \( Sp(2N-2, \mathbb{Z}) \) consists of all \( (2N-2) \times (2N-2) \) integer matrices \( M \) satisfying \( M \cdot I \cdot \tilde{M} = I \) where \( I = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \) is the symplectic metric. The \( (2N-2) \)-component vector of scalar fields, \( a \), as well as the vector of charges \( n \) (thought of as column vectors),

\[ \begin{pmatrix} a^i_D \\ a_j \end{pmatrix}, \quad \begin{pmatrix} h_i \\ q^j \end{pmatrix}, \] (2.6)
transform under $M \in Sp(2N - 2, \mathbb{Z})$ as

$$a \to M \cdot a, \quad n \to t^\dagger M^{-1} \cdot n. \quad (2.7)$$

In a vacuum with massless charged particles, the $U(1)$'s that couple to them will flow to zero coupling in the infrared and will be well-described by perturbation theory. We use this to compute the monodromy around a submanifold of such vacua in moduli space. Consider the case of a submanifold along which one dyon of charge $n$ is massless. There exists a duality transformation which takes this to a state with an electric charge $q^1 = \gcd(n_i)$ with respect to the first $U(1)$ factor, say, and otherwise uncharged both electrically and magnetically. Thus, in these coordinates, by (2.5), the submanifold along which this dyon is massless is given locally by $a_1 = 0$, and the other $a_i$ vary along this submanifold. For $a_1 \to 0$, the leading $a_1$ dependence of the effective couplings $\tau^{ij}$ is determined to be

$$\tau^{ij} = \delta_i^1 \delta_j^1 \frac{(q^1)^2}{2\pi i} \log(q^1 a_1) + \mathcal{O}(a_1^0), \quad (2.8)$$

by a one-loop computation in the effective theory. Integrating, using (2.3), gives

$$a_D^j = \delta_j^1 \frac{(q_1)^2 a_1}{2\pi i} \log(q^1 a_1) + \mathcal{O}(a_1^0). \quad (2.9)$$

Then, the monodromy $M$ around a path $\gamma(t) = \{a_1(\theta) = e^{i\theta}, a_j = \text{constant}, j \neq 1\}$, which encircles the $a_1 = 0$ submanifold, is then easily computed from (2.7) to be

$$M = \begin{pmatrix} 1 & (q^1)^2 e_{11} \\ 0 & 1 \end{pmatrix}, \quad (2.10)$$

where $(e_{11})^{ij} \equiv \delta_i^1 \delta_j^1$. Converting back to the original description of the physics in which the charge of the massless dyon was $n$ by the inverse duality transformation, gives the general form for the monodromy around a massless dyon singularity to be

$$M = \mathbb{1} + n \otimes t^\dagger (I \cdot n) = \begin{pmatrix} \mathbb{1} + q^i h_j & q^j q^i \\ -h_i h_j & \mathbb{1} - h_i q^j \end{pmatrix}. \quad (2.11)$$

The condition on the charges for two dyons to be mutually local is that they be symplectically orthogonal—c.f. Eq. (1.1):

$$0 = t^\dagger n^{(1)} \cdot I \cdot n^{(2)} = h^{(1)} \cdot q^{(2)} - h^{(2)} \cdot q^{(1)}. \quad (2.12)$$
This is equivalent to the condition that their associated monodromies (2.11) commute:

\[ [M^{(1)}, M^{(2)}] = 0. \] (2.13)

When the constraint (2.12) is satisfied, there exists a symplectic transformation to dual fields where each dyon is now described as an electron charged with respect to only one dual low energy \( U(1) \): \( h^{(i)} \to 0 \) and \( q^{(i)j} \to \delta^{i,j} \gcd(n_k^{(i)}) \). Note that there can at most be \( N - 1 \) linearly independent charge vectors satisfying (2.12).

2.2. \( SU(N) \) Solution

The solution \([3,4]\) for the effective prepotential \( \mathcal{F} \) is most simply expressed in terms of an auxiliary Riemann surface \( \mathcal{C} \) which varies over the moduli space, defined by the curve

\[
y^2 = P(x)^2 - \Lambda^{2N} \]

\[
P(x) \equiv \frac{1}{2} \det(x - \langle \phi \rangle) = \frac{1}{2} \sum_{\ell} (-1)^\ell s_\ell x^{N-\ell}. \] (2.14)

\( \mathcal{C} \) is a genus \( N - 1 \) Riemann surface realized as a two-sheeted cover of the complex \( x \)-plane branched over \( 2N \) points. Choose a basis of \( 2N - 2 \) one-cycles \( (\alpha_i, \beta_j) \) on \( \mathcal{C} \) with the standard intersection form \( \langle \alpha_i, \beta_j \rangle = \delta_{ij}, \langle \alpha_i, \alpha_j \rangle = \langle \beta_i, \beta_j \rangle = 0 \). The \( (a_{Di}, a_j) \) are then integrals of the meromorphic form

\[
\lambda = \frac{1}{2\pi i} \frac{\partial P(x)}{\partial x} \frac{x \, dx}{y} \] (2.15)

over the \( (\alpha_i, \beta_j) \) cycles \( [3] \). Defining the matrices

\[
A^i_\ell \equiv \frac{\partial a^i_D}{\partial s_\ell} = \oint_{\alpha_i} \lambda_\ell, \quad B^j_\ell \equiv \frac{\partial a^j_j}{\partial s_\ell} = \oint_{\beta_j} \lambda_\ell, \] (2.16)

where \( \lambda_\ell = \partial \lambda/\partial s_\ell \) form a basis of the \( N - 1 \) independent holomorphic one-forms on \( \mathcal{C} \), the matrix of \( U(1) \) effective couplings is given by

\[
\tau^{ij} = \sum_{\ell} A^i_\ell (B^{-1})^{\ell j}, \] (2.17)

which is just the period matrix of the Riemann surface \( \mathcal{C} \).
The moduli space contains submanifolds along which a charged particle becomes massless. By the mass formula (2.5) and since the one-form \( \lambda \) (2.15) is non-singular at the branch points, the only way this can happen is for cycles of the curve \( C \) to degenerate. This occurs whenever two or more of the zeros of the polynomial \( Q(x) \equiv P(x)^2 - \Lambda^{2N} \) coincide. These degenerations are given by the vanishing of the discriminant of the polynomial, defined by \( \Delta(Q) \equiv \prod_{m>n}(e_m - e_n)^2 \), where the \( e_m \) are the \( 2N \) zeros of \( Q(x) \). \( Q \) factorizes as \( Q = Q_+ Q_- \) with

\[
Q_\pm(x) = P(x) \pm \Lambda^N. 
\] (2.18)

Denote the zeros of \( Q_\pm \) by \( e_i^\pm \). Then, from its definition, the discriminant of \( Q \) is \( \Delta(Q) = \Delta(Q_+)\Delta(Q_-) \prod_{i,j}(e_i^+ - e_j^-)^2 = \Delta(Q_+)\Delta(Q_-) \prod_i Q_+(e_i^-)^2 \). Since \( Q_+ - Q_- = 2\Lambda^N \), \( Q_+(e_i^-) = 2\Lambda^N \), so the discriminant factorizes

\[
\Delta(Q) = 2^{2N} \Lambda^{2N^2} \Delta(Q_+) \Delta(Q_-). 
\] (2.19)

Thus there are always two separate codimension one singular submanifolds in moduli space, described by the vanishing of \( \Delta(Q_\pm) \). As we will see later, these two submanifolds each correspond to one of the two singular points in the \( SU(2) \) moduli space, which is embedded in a complicated way in the \( SU(N) \) moduli space at weak coupling.

### 2.3. SU(3) Moduli Space

We now specialize to the \( SU(3) \) case, and denote the good global coordinates on its moduli space by

\[
u \equiv -s_2 = -\phi_1 \phi_2 - \phi_1 \phi_3 - \phi_2 \phi_3, \quad v \equiv s_3 = \phi_1 \phi_2 \phi_3. 
\] (2.20)

Note that there is a \( \mathbb{Z}_6 \) spontaneously broken discrete global symmetry whose action on the \( SU(3) \) moduli space is generated by \( u \rightarrow e^{2\pi i/3} u, \ v \rightarrow e^{i\pi} v \). We find from (2.14)

\[
\Delta(Q_\pm) = 4u^3 - 27(v \pm 2\Lambda^3)^2. 
\] (2.21)

The two submanifolds \( \Delta(Q_\pm) = 0 \) intersect at the three points \( v = 0, \ u^3 = (3\Lambda^2)^3 \). These points, which we refer to as the ‘\( \mathbb{Z}_2 \) vacua’ since each leaves a \( \mathbb{Z}_2 \subset \mathbb{Z}_6 \) unbroken,
correspond to vacua where two mutually local dyons are simultaneously massless. Their physics was studied in detail in [3,5]. Upon breaking $N = 2$ to $N = 1$ supersymmetry by relevant or marginal terms in the superpotential, these points are not lifted, and so correspond to the three discrete vacua of the $N = 1$ $SU(3)$ theory.

In addition to these these intersection points, there are also singular points of each curve individually: e.g. points at which $\partial \Delta(Q_+)/\partial u = \partial \Delta(Q_+)/\partial v = 0$. There is one such point on the $\Delta(Q_+)$ curve: $u = 0$, $v = -2\Lambda^3$. A similar point with $v \to -v$ occurs on the $\Delta(Q_-)$ curve. These points, which we refer to as the ‘$Z_3$ vacua’ since they leave unbroken a $Z_3 \subset Z_6$, will be examined in detail below.

In the remainder of this section, we build up a picture of the $SU(3)$ moduli space and how the $\Delta(Q_\pm) = 0$ curves sit in it. We do this by presenting three-dimensional slices of the four-(real)-dimensional $SU(3)$ moduli space. This moduli space is $\mathbb{C}^2$, parametrized by the two complex coordinates $u, v$. One nice slice [15] of this space is the hypersurface $\text{Im} v = 0$, shown in Fig. 1.

![Fig. 1: The Imv = 0 hypersurface in SU(3) moduli space. The heavy solid curves are its intersection with the surface of massless dyons $\Delta(Q_-) = 0$, and the dotted curve with the massless dyon surface $\Delta(Q_+) = 0$. The solid circles mark the $Z_2$ vacua, while the open circles denote the $Z_3$ vacua.](image)

The $Z_2$ points are seen to correspond to the transverse intersection of two one-complex-dimensional surfaces in $\mathbb{C}^2$, as expected. The nature of the $Z_3$ points is less clear, however. A better understanding of the $Z_3$ points can be obtained by slicing the moduli space by a 3-sphere surrounding one of these points. The $\Delta(Q_\pm)$ curves (2.21)
near these points take a simple form upon shifting $\tilde{v} \equiv v \pm 2\Lambda^3$:
\[ 4u^3 = 27\tilde{v}^2. \tag{2.22} \]

Consider the intersection of this surface with the hypersurface $4|u|^3 + 27|\tilde{v}|^2 = R^6$ which is topologically a 3-sphere. The norm of (2.22) implies that $4|u|^3 = 27|\tilde{v}|^2 = \frac{1}{2}R^6$, leaving the torus of phases of $\psi_u \equiv \arg u$ and $\psi_v \equiv \arg \tilde{v}$ unconstrained. The argument of (2.22) implies $3\psi_u = 2\psi_v \pmod{2\pi}$, whose solution is a curve which winds three times around the torus in one direction while it winds twice in the other—the knot shown in Fig. 2.

There are in principle two independent $Sp(4,\mathbb{Z})$ monodromies that could occur along paths around such a knot. This can be seen as follows. Consider the monodromies $M_i$ around the three paths $\gamma_i$ indicated in Fig. 2. Deform $\gamma_1$ by sliding it along the knot, to become $\gamma_3$ except for its wrapping around the part of the knot that $\gamma_2$ encircles. Thus $\gamma_1 \simeq \gamma_2 \cdot \gamma_3 \cdot \gamma_2^{-1}$, as well as cyclic permutations. This implies the corresponding relations for their monodromies
\[ M_i M_{i+1} = M_{i+1} M_{i+2}, \tag{2.23} \]
which in turn imply that all the monodromies around the knot can be generated by just two monodromies, say $M_1$ and $M_2$, which are constrained to satisfy $M_1 M_2 M_1 = M_2 M_1 M_2$.

![Fig. 2: The heavy lines are the stereographic projection of the intersection of a 3-sphere centered on a $\mathbb{Z}_3$ point with the corresponding massless dyon curve $\Delta(Q_\pm) = 0$. The lighter curves are three convenient paths encircling the knot.](image_url)
Note that either the resulting monodromies do not commute or they are the same. Which of these two possibilities occurs is a matter of computation of the monodromies realized by the actual degeneration of the Riemann surface $C$ (2.14) near a $\mathbb{Z}_3$ point. It turns out that $M_1 \neq M_2$ and thus that the dyons going massless at the $\mathbb{Z}_3$ points are indeed mutually nonlocal. One easy way of seeing this is to note that the monodromies around the $\Delta(Q_{\pm}) = 0$ curves have been computed in Ref. [15] at weak coupling far from the $\mathbb{Z}_3$ points (at large $Re v$ in Fig. 1), and that there is no obstruction to deforming their defining paths down to the $\mathbb{Z}_3$ point. With the notation $n^{(i)} = (h_1^{(i)}, h_2^{(i)}; q_1^{(i)}, q_2^{(i)})$, the charges of the massless dyons corresponding to shrinking the $\gamma_i$ were found to be $[15]$

\[
\begin{align*}
n^{(1)} &= (1, 0; 1, 0), \\
n^{(2)} &= (0, 1; -1, 1), \\
n^{(3)} &= (1, 1; 0, 1),
\end{align*}
\]

which are indeed not mutually local (and only two are linearly independent). Alternatively, one can calculate the monodromies directly from the curve (2.14) near a $\mathbb{Z}_3$ point to find the same answer (up to a duality basis transformation).

There is a symplectic transformation to a basis in which the charges are

\[
\begin{align*}
n^{(1)} &= (1, 0; 0, 0), \\
n^{(2)} &= (0, 0; -1, 0), \\
n^{(3)} &= (1, 0; -1, 0),
\end{align*}
\]

In this basis we have one electron, one monopole, and one dyon, all charged with respect to only the first $U(1)$ factor.

2.4. Generalization to $SU(N)$

The topology of the singular submanifolds of the $SU(N)$ moduli spaces for $N > 3$ is much more complicated and harder to analyze. For example, the $SU(4)$ moduli space is 3-dimensional (we use only complex dimensions in this paragraph) and there are still two 2-dimensional submanifolds $\Delta(Q_{\pm}) = 0$ where a single dyon becomes massless. These can intersect along 1-dimensional submanifolds where two mutually-local dyons become massless. Also, there will be 1-dimensional submanifolds of transverse self-intersections of the $\Delta(Q_{\pm}) = 0$ curves (where again two mutually local dyons must become massless—see the discussion in the next section). The 0-dimensional manifolds where these self-intersections intersect the other $\Delta(Q_{\pm}) = 0$ curve are a set of four isolated points where
the maximal number of three mutually local dyons are massless. These points, and their $SU(N)$ generalizations, were described in [5].

Since at weak coupling the $SU(3)$ moduli space $M_3$ is locally embedded in the $SU(4)$ moduli space as $\mathbb{C} \times M_3$, the $\mathbb{Z}_3$ vacua of $M_3$ will give rise to a whole 1-dimensional curve of such singularities. This curve itself has a cusp-like singularity. Such extra-cuspy points are in some sense the $SU(4)$ analogs of the $\mathbb{Z}_3$ points for $SU(3)$.

The simplest examples are the $SU(N)$ points $P(x) = \frac{1}{2} x^N \pm \Lambda^N$. At these points, at least $N - 1$ mutually non-local dyons with linearly independent charges become massless. They are charged with respect to half (for $N$ odd, or $N/2$ for $N$ even) of the $U(1)$ factors.

3. Existence of Nonlocal Points

In this section we show that the combination of the Seiberg–Witten solution [2] of $\mathcal{N} = 2$ $SU(2)$ gauge theory, and the way the $SU(2)$ moduli space is embedded in the $SU(3)$ moduli space at weak coupling implies that some sort of vacua with massless mutually non-local dyons (like the $\mathbb{Z}_3$ vacua) must exist.

The strategy for the argument will be to consider the intersection of $SU(3)$ moduli space with a large 3-sphere where perturbation theory reliably computes the embedding of the $SU(2)$ moduli space in the $SU(3)$ moduli space. Using the Seiberg-Witten solution then gives the topology and monodromies of the one-real-dimensional singular curves on the 3-sphere where a dyon becomes massless. We then shrink the 3-sphere, sweeping out the whole of the $SU(3)$ moduli space. The singular curves will deform continuously along this family of 3-spheres, except for isolated points where the curves may cross (or small loops may shrink to a point and disappear). By continuity, the monodromies around the curves remain unchanged since $Sp(4, \mathbb{Z})$ is discrete. This is true even when there is a crossing of curves, since the monodromy can be measured along a path that loops around the curve anywhere along its length, while the crossing takes place at a single point.

As we show below, the singular curves on the large 3-sphere are knotted and have non-commuting monodromies around different sections of the same curve, just as in the case of the knotted curve in Fig. 2. Now, imagine that we shrink the large 3-sphere to
a point in moduli space that does not lie on any singular surface. Then the curves must eventually shrink to points until they have entirely disappeared (since a sufficiently small 3-sphere about the final point does not intersect any singular curve, by construction). But since there are non-commuting monodromies about different segments of a single curve, by continuity there must be at least one crossing or degeneration where the parts of the curve with non-commuting monodromies meet. Such a point corresponds to a vacuum with massless mutually non-local dyons, whose existence we sought to prove.

This argument assumes that the large three-sphere is contractible in moduli space. Perhaps the correct moduli space is not $\mathbb{C}^2$, but some topologically non-trivial space? The simplest example would be $\mathbb{C}^2$ minus the points with mutually non-local massless particles. In other words, perhaps the $\mathbb{Z}_3$ points in the $SU(3)$ moduli space are really ‘points at infinity’ and so should not be considered consistent vacua. However, there will be vacua with mutually non-local particles as light as one likes, and one is still faced with the problem of making sense of such a theory. Indeed, this will be the gist of our analysis in later sections: to understand what constraints there are on the possible physics at the $\mathbb{Z}_3$ points by looking at the $U(1) \times U(1)$ vacua arbitrarily close to them.

One might also imagine that the moduli space has a more complicated topology, presumably a branched cover of $\mathbb{C}^2$. One would need to propose a physical interpretation of the branch points and, since each of the covering sheets has a semiclassical limit, identify the observable distinguishing them in this limit. We did not find a scenario of this sort.

We now proceed to the determination of the topology and monodromies of the singular curves on the large 3-sphere. Afterwards we include a discussion designed to make the topological aspects of the above argument more concrete.

3.1. $SU(2)$ in $SU(3)$ at Weak Coupling

Classically, the singularities which reach out to infinity in $SU(3)$ moduli space are those where $\langle \phi \rangle$ breaks $SU(3) \to U(1) \times SU(2)$. This occurs whenever two $\langle \phi \rangle$ eigenvalues are the same, which, in gauge invariant coordinates, is the curve

$$4u^3 = 27v^2.$$  

(3.1)
As this is the same as the curve (2.22) found near the $\mathbb{Z}_3$ vacua, its intersection with a 3-sphere centered on $u = v = 0$ will be the same knot, shown in Fig. 2.

Quantum corrections modify this classical picture qualitatively, since near the $SU(2)$ singularity (3.1) the low-energy physics is strongly coupled. Parametrize the eigenvalues of $\langle \phi \rangle$ as \( \{M + a, M - a, -2M\} \), implying

\[
u = 3M^2 + a^2, \quad v = -2M(M^2 - a^2).
\] (3.2)

For $|M| \gg |a|$, this vev breaks $SU(3)$ in two stages: $SU(3) \to U(1) \times [SU(2)^2 U(1)]$. For $|M| \gg |\Lambda|$, the first $U(1)$ factor decouples and the low-energy physics is effectively described by an $\mathcal{N} = 2$ $SU(2)$ gauge theory spontaneously broken by the adjoint scalar vev $\langle \phi \rangle \sim (a \ 0 \ 0)$, where $a \neq 0$. This theory was solved by Seiberg and Witten [2] who found that instead of a single singularity at $a^2 = 0$ (where classically $SU(2)$ would be restored), there are two singularities at $a^2 = \pm \tilde{\Lambda}^2$ where certain dyons are massless. Here $\tilde{\Lambda}$ is the $SU(2)$ strong-coupling scale. Thus, the single classical curve (3.1) is split quantum-mechanically into two curves. In terms of its intersection with a large 3-sphere, this means that the single knot of Fig. 2 is split into two linked knots.

The precise way these two knots are linked is fixed by the relation of $\tilde{\Lambda}$ to $\Lambda$, determined by the renormalization group matching $\Lambda^3 \sim M\tilde{\Lambda}^2$. This implies that the $SU(2)$ dyon singularities occur at $a^2 = \pm \Lambda^3/M$. Plugging into (3.2) and eliminating $M$ gives the equations for the singular curves

\[
4u^3 = 27(v^2 \mp 8v\Lambda^3) + \mathcal{O}(\Lambda^6).
\] (3.3)

The intersection of these two curves with a 3-sphere of radius much larger than $|\Lambda|$ gives the two knots linked as shown in Fig. 3.

We would now like to compute the monodromies along paths $\gamma_i$ looping around the knots, shown in Fig. 3. On the one hand, they can be calculated directly from the one-loop expression for the $SU(3)$ effective action (giving the monodromies along paths $\gamma_i \cdot \gamma_{i+3}$ which go around both knots), and the monodromies of the exact $SU(2)$ solution (which tell how the $\gamma_i \cdot \gamma_{i+3}$ monodromies must factorize into the individual monodromies around each knot separately). On the other hand, since it was shown in Ref. [3] that the curve (2.14)
reproduces the field theory monodromies at weak coupling, we can borrow the results of Ref. \[15\] which calculated those monodromies from (2.14). Identifying the monodromies in terms of the magnetic and electric charges \(n^{(i)}(h^{(i)}; q^{(i)})\) of the massless dyon on the curve encircled by the path \(\gamma_i\), one has:

\[
\begin{align*}
\gamma^{(1)} &= (1, 0; 1, 0), \\
\gamma^{(2)} &= (0, 1; -1, 1), \\
\gamma^{(3)} &= (1, 1; 0, 1), \\
\gamma^{(4)} &= (1, 0; -1, 1), \\
\gamma^{(5)} &= (0, 1; 0, -1), \\
\gamma^{(6)} &= (1, 1; -1, 0).
\end{align*}
\]

As there are charges on a single curve which are not mutually local, for example \(\gamma^{(1)} \cdot I \cdot \gamma^{(2)} \neq 0\), we have completed the argument showing that vacua with massless mutually non-local dyons must occur in the \(SU(3)\) (and therefore \(SU(N)\)) theories.

3.2. Degenerations and Monodromies

We now discuss the way the singular curves on our 3-sphere may cross or otherwise degenerate as the 3-sphere is deformed, and what monodromies are allowed at these degenerations. This discussion is not necessary for the argument completed above, but it may serve to make some of its topological aspects more concrete.
3–dimensional slices of 2–dimensional surfaces in a 4–dimensional space are generically 1–dimensional curves. As the 3–dimensional slice is deformed the curves move, and two such curves may touch at a point. The stable sequences of such degenerations are shown in Fig. 4. ‘Stable’ here means that the degeneration can not be removed by any small deformation of the curves. The (a) and (b) degenerations depicted in Fig. 4 can be visualized in three dimensions as a sequence of intersections of a plane with a sphere as the plane lifts off the sphere, for (a), and as a plane passing through the saddle point of a saddle (b). This shows that there is actually no invariant meaning to the degeneration point in cases (a) and (b). The (c) degeneration, on the other hand, is a truly 4–dimensional phenomenon, being the depiction of the transverse intersection at a point of two 2–dimensional surfaces. In this case the degeneration point is the point of intersection, and has a slice-independent meaning.

![Diagrams of degenerations](https://example.com/degenerations.png)

**Fig. 4:** The three stable degenerations of curves in a 3–dimensional space. When viewed as the intersection of 2–surfaces with a sequence of 3–dimensional slices of a 4–dimensional space, only in case (c) does the point of intersection have a slice-invariant meaning.

The existence of such degenerations constrains the possible monodromies around these curves. For example, around the two paths $\gamma_1, \gamma_2$ marked in Fig. 4(c), there may, in principle be two independent monodromies $M_1$ and $M_2$. However, a sequence of deformations of $\gamma_1$ as we pass through the degeneration and then back again shows (see Fig. 5) that $\gamma_1 = \gamma_2 \cdot \gamma_1 \cdot \gamma_2^{-1}$, and thus that $[M_1, M_2] = 0$. Thus only surfaces with mutually local massless dyons are allowed to intersect transversely. Simpler sequences of path defor-
mations show in the (a) and (b) degeneration cases that there is only one independent monodromy, consistent with the fact that these degenerations result from a sequence of 3–surfaces slicing a single smooth 2–surface.

\[ \begin{align*} 
\gamma_1 & \quad \rightarrow \quad \gamma_1 \cdot \gamma_1^{-1} \\
\gamma_2 & \quad \rightarrow \quad \gamma_2 \cdot \gamma_2^{-1} \\
\gamma_3 & \quad \rightarrow \quad \gamma_3 \cdot \gamma_3^{-1} 
\end{align*} \]

**Fig. 5:** Deformation of the $\gamma_1$ path to the path $\gamma_2 \cdot \gamma_1 \cdot \gamma_2^{-1}$ in the vicinity of the crossing depicted in Fig. 4(c).

One can now see how the two knotted curves at weak coupling shown in Fig. 3 can unlink as we shrink the 3-sphere to stronger couplings: the knot represented by a dotted line shrinks until its three loops cross the other (solid) knot in three places. These type (c) crossings are allowed, because (3.4) implies that the relevant monodromies commute: \([M_1, M_5] = [M_2, M_6] = [M_3, M_4] = 0\). Indeed, these three crossings correspond to the three $\mathbb{Z}_2$ vacua with mutually local massless dyons found from the curve (2.14). The two unlinked knots can not unknot by any of the stable degenerations of Fig. 4, since we have shown that those degenerations do not support non-commuting monodromies. Thus the unknotting must occur via an unstable degeneration of some sort. It is not hard to see that of all the degenerations involving three curves, only the one shown in Fig. 6 allows monodromies satisfying the constraints (2.23) implied by the topology of the knot. This degeneration is in fact the one that occurs at the $\mathbb{Z}_3$ vacua with mutually non-local massless dyons found above from the exact solution (2.14) of the $SU(3)$ theory.

4. **Effective Lagrangian near the $\mathbb{Z}_3$ Vacua**

The low-energy effective Lagrangian of $\mathcal{N} = 2$ $SU(3)$ gauge theory, written in terms of two $U(1)$ gauge multiplets and the hypermultiplets for the light matter in that region
Fig. 6: An unstable crossing of three curves at a point in three dimensions. This can be viewed as successive 3-dimensional slices through the massless dyon 2-surfaces in the neighborhood of a $\mathbb{Z}_3$ point in the $SU(3)$ moduli space.

of moduli space, was given in (2.2), (2.3) and (2.4). The effective couplings were given by derivatives of an analytic prepotential $F$. One can choose any two symplectically orthogonal charge vectors as the gauge charges with local couplings, and ordinarily one does this to make the couplings to the hypermultiplets local.

Near the $\mathbb{Z}_3$ point, two non-symplectically orthogonal periods become small: call them $a_1$ and $a_D^1$. These correspond to the mutually non-local monopoles which become massless there, since all masses of light particles are determined by these two “short” periods. To write the matter Lagrangian we need the non-symplectically orthogonal gauge multiplets $(A_1, W_1)$ and $(A_D^1, W_D^1)$, containing non-locally related vector potentials. We will see below that $a_1$ and $a_D^1$ are good coordinates in this region of moduli space. To write a standard $\mathcal{N} = 2$ Lagrangian (in terms of mutually local fields) we must choose one of the short periods, say $A_1$, and one of the “long” periods $A_2$ as our variables. We then have $A_D^1 = \partial F(A_1, A_2)/\partial A_1$ by (2.3).

The gauge kinetic term is then determined by $\tau^{ij}$, the period matrix of the $SU(3)$ quantum curve

$$y^2 = P(x)^2 - \Lambda^6$$

$$P(x) = \frac{1}{2} (x^3 - ux - v)$$

(4.1)

near one of the $\mathbb{Z}_3$ points $u = 0, v = \pm 2\Lambda^3$. Near the $\mathbb{Z}_3$ point with $v = 2\Lambda^3$, the branch points satisfy $x^3 - \delta u x - 2\Lambda^3 - \delta v = \pm 2\Lambda^3$. Taking the minus sign, we see the degenerating branch points approach $x = 0$ as

$$x^3 - \delta u x - \delta v = 0,$$

(4.2)

while the plus sign gives three branch points at $x^3 = 4$. These six branch points and a choice of basis of conjugate cycles is shown in Fig. 7.
Fig. 7: The distribution of the six branch points in the $x$-plane near a $\mathbb{Z}_3$ point. Three points are of order $\delta u^{1/2}$ or $\delta v^{1/3}$ from the origin, while the other three are close to $x = e^{2\pi i k/3} 2^{2/3} \Lambda$. The dotted lines are a choice of branch cuts, and a basis of conjugate cycles is shown, with the solid and dashed lines on the first and second sheets.

The short periods $(a_1, a_D^1)$ and the long periods $(a_2, a_D^2)$ are given by

$$a_i = \oint_{\alpha_i} \lambda, \quad a_D^i = \oint_{\beta_i} \lambda,$$

(4.3)

where the one-form $\lambda$ is given by (2.15). Near the $\mathbb{Z}_3$ point as the short periods vanish, the corresponding light states are in this basis an electron with mass $|a_1|$, a monopole with mass $|a_D^1|$, and a dyon of mass $|a_1 + a_D^1|$. These are all charged only with respect to the first $U(1)$ factor.

Close to the $\mathbb{Z}_3$ point, the two pairs of conjugate cycles $(\alpha_1, \beta_1)$ and $(\alpha_2, \beta_2)$ are separated by a “neck” whose conformal parameter is becoming large, as illustrated in Fig. 8. This degeneration of a genus two Riemann surface was studied in [16] and several of the following results are derived there. This is a familiar limit in string theory and would correspond there to two ‘one-loop tadpole’ amplitudes connected by a zero momentum propagator. In this basis the period matrix $\tau^{ij}$ splits at the degeneration point as

$$\tau^{ij} = \begin{pmatrix} \tau^{11} & 0 \\ 0 & \tau^{22} \end{pmatrix}$$

(4.4)
where $\tau^{11}$ is the modulus of the “small” torus and $\tau^{22}$ is the modulus of the “large” torus.

The ‘large’ torus is obtained by simply identifying the three degenerating points and taking a double cover of the resulting surface with four punctures. Thus, near the $\mathbb{Z}_3$ point it will be described by the curve $w^2 = x(x^3 - 4\Lambda^3)$ plus order $\delta u/\Lambda^2$ and and $\delta v/\Lambda^3$ corrections. Because of the $\mathbb{Z}_3$ symmetry of this curve as $\delta u, \delta v \to 0$, near the $\mathbb{Z}_3$ point the modulus of the large torus is

$$
\tau^{22} = e^{2\pi i/6} + O\left(\frac{\delta u}{\Lambda^2}\right) + O\left(\frac{\delta v}{\Lambda^3}\right).
$$

(4.5)

The “small” torus can be obtained similarly after a conformal transformation; it is described by the curve

$$
w^2 = x^3 - \delta ux - \delta v
$$

(4.6)

plus order $\delta u/\Lambda^2$ and $\delta v/\Lambda^3$ corrections near the $\mathbb{Z}_3$ point. In the limit its modulus is

$$
\tau^{11} = \tau(\rho) + O\left(\frac{\delta u}{\Lambda^2}\right) + O\left(\frac{\delta v}{\Lambda^3}\right).
$$

(4.7)

The function $\tau$ depends only on $\rho^3 \equiv \delta u^3/\delta v^2$ (as can be seen by rescaling $x$), or equivalently, the angles of the triangle formed by the degenerating points.

The monodromy around a path encircling, say, the $a_1 = 0$ curve near the $\mathbb{Z}_3$ point take $a_1 \to e^{2\pi i}a_1$, $a_D^1 \to a_D^1 + a_1$, and leaves the long periods unchanged. Since the action of this monodromy on $\tau^{ij}$ is to shift only $\tau^{11} \to \tau^{11} + 1$ and leave $\tau^{12}$ and $\tau^{22}$ unchanged, we see that the off-diagonal terms of the period matrix are analytic in the short periods. Since the period matrix splits, the off-diagonal terms must also vanish at the $\mathbb{Z}_3$ point, so
we have

$$\tau^{12} = \tau^{21} = \mathcal{O}\left(\frac{a_1}{\Lambda}\right) + \mathcal{O}\left(\frac{a_D^1}{\Lambda}\right).$$  \hspace{1cm} (4.8)$$

Physically, the splitting of the period matrix will mean that the two $U(1)$ gauge factors decouple. Integrals of $\lambda$ over the long periods will all be $O(\Lambda)$ and thus all particles with charge in the second $U(1)$ will have masses of $O(\Lambda)$. On the other hand, particles with charge only in the first $U(1)$ will have masses going to zero in the limit, producing a separation in scales between the two sectors. Let us keep this in mind, but defer most of the physical interpretation to the next subsection.

We thus need to compute $\tau$, $a_1$, $a_D^1$ and $a_2$ as functions of $\delta u$ and $\delta v$, and then re-express $\tau$ in terms of $a_2$ and one of the short periods. The long period $a_2$ depends analytically on these parameters: $a_2 \sim \Lambda + \delta u/\Lambda + \delta v/\Lambda^2 + \ldots$. When the separation of scales is large, this dependence will be weak and we can trade $\delta u$ for $a_2$.

Useful parameters for the small torus are $\delta v = 2\epsilon^3$ and $\delta u = 3\epsilon^2\rho$. The overall mass scale is $\epsilon$, while the dimensionless $\rho$ determines the modulus of the small torus in the limit: rescaling $x = \epsilon z$, the defining equation of the small torus near the $\mathbb{Z}_3$ point (4.6) becomes

$$w^2 = z^3 - 3\rho z - 2,$$

depends only on $\rho$ and not on $\epsilon$. The natural dimensionless parameter is actually $\rho^3$ since the moduli space of the curve (4.3) has a $\mathbb{Z}_3$ symmetry $\rho \rightarrow e^{2\pi i/3}\rho$. The interesting points in its moduli space are as follows: the degeneration of the small torus at $\rho^3 = 1$, the point $\rho^3 = 0$ where the small torus has a $\mathbb{Z}_3$ symmetry, and the point $\rho^3 = \infty$ where it has a $\mathbb{Z}_2$ symmetry (rescale $z \rightarrow \rho^{1/2}z$ to see this behavior). The $\rho^3$ plane is an $SL(2, \mathbb{C})$ transformation of the $j$ (fundamental modular invariant) plane, $j = 27 \cdot 64 \rho^3/(\rho^3 - 1)$.

We wish to compute the periods of the form $\lambda \propto (x/y)dP$ on the small torus. It degenerates to

$$\lambda \propto \frac{\epsilon^{5/2}}{\Lambda^{3/2}} \frac{z(z^2 - \rho)}{w} dz = \frac{\epsilon^{5/2}}{\Lambda^{3/2}} w \ dz + d(\ldots),$$

on (4.9). We will start by examining the periods near $\rho^3 = 1$, $\infty$, and 0, in turn.

If $\rho$ is near a degeneration of the small torus, $\rho^3 = 1 + \delta \rho$, the three branch points are at $z = -1 \pm \mathcal{O}(\delta \rho^{1/2})$ and $z = 2 + \mathcal{O}(\delta \rho)$. Call the periods $a_s$ and $a_l$ with $|a_s| \leq |a_l|$. 

21
Then, from (4.10), one finds
\[ a_s \propto (\delta \rho) \frac{\epsilon^{5/2}}{\Lambda^{3/2}}, \quad a_l \propto \frac{\epsilon^{5/2}}{\Lambda^{3/2}}. \] (4.11)
Thus we find that one of the three light hypermultiplets has a mass
\[ m_s / \Lambda \sim \delta \rho (\epsilon / \Lambda)^{5/2}, \] while the other two have masses
\[ m_l \sim (\epsilon / \Lambda)^{5/2}. \] Which of the three particles is lightest depends on which root of \( \rho^3 = 1 \) we are expanding about: the \( \mathbb{Z}_3 \) symmetry of the small torus (4.9) acts on the periods as \( a_1 \rightarrow a_1^D \rightarrow -a_1 - a_1^D \).

The modulus \( \tau(\rho) \) of the small torus in this limit can be determined from the monodromies to be
\[ \tau = \frac{1}{2\pi i} \log \frac{a_s}{a_l} + \ldots \] (4.12) since, as mentioned above, along a path \( a_1 \rightarrow e^{2\pi i} a_1 \) encircling the \( a_1 = 0 \) curve near the \( \mathbb{Z}_3 \) point \( \tau \rightarrow \tau + 1 \). Taking \( a_1 = a_s \), this gives (4.12), since \( \tau \) depends only on \( \rho \). Alternatively, one can calculate (4.12) directly from the definition of the modulus in terms of the periods of the holomorphic one-form \( dz/w \) on the small torus: \( \tau = \oint_{\beta_1} \frac{dz}{w} / \oint_{\alpha_1} \frac{dz}{w} \).

The most important feature of the result is that the final low energy coupling is independent of \( \epsilon / \Lambda \), which scaled out of the modulus of the small torus. This is true for all \( \rho \). We save a detailed discussion of the physical interpretation for the next section, but the simplest interpretation of this result is that it comes from integrating the beta function for a single charge one hypermultiplet, turning on at the scale \( a_l \), the mass of the two heavier particles, and turning off at the scale \( a_s \), the mass of the light particle.

The limit in which \( \rho \rightarrow \infty \) is also interesting. This limit sends two of the branch points of the small torus to infinity as \( z \sim \pm \sqrt{\rho} \), while the third stays at the origin. Therefore, this is is not a degeneration, because it can be undone by the rescaling \( z \rightarrow \rho^{1/2} z \). The limit is the torus with modulus \( \tau = i \) and \( \mathbb{Z}_2 \) symmetry. The periods are \( a_\pm = C(\epsilon^2 \rho)^{5/4} / \Lambda^{3/2} i^{\pm 1/2} \) and the three particles have mass \( |a|, |a| \) and \( \sqrt{2}|a| \).

Finally, taking \( \rho = 0 \) produces a small torus with \( \mathbb{Z}_3 \) symmetry, and modulus \( \tau = e^{2\pi i/3} \). The periods are \( a_1 = e^{2\pi i/3} a_D^1 = C' \epsilon (\epsilon / \Lambda)^{3/2} \) and all three particle masses are equal.

In summary, we have developed a picture of the vicinity of the \( \mathbb{Z}_3 \) point, shown in Fig. 9. The limit \( \epsilon / \Lambda \rightarrow 0 \) takes us to the \( \mathbb{Z}_3 \) point, and varying \( \rho \) changes the direction from
which we approach it. The masses all vary with $\epsilon$ as $m \sim (|a_1|, |a_D^1|, |a_1 + a_D^1|) \sim \epsilon^{5/2} / \Lambda^{3/2}$.

The $\text{Im} a_D^1 / a_1 = 0$ curve will be determined below.

4.1. Elliptic function representation

To describe the whole moduli space, a representation in terms of elliptic functions is useful [17].

The parameters describing the small torus, $\delta u$ and $\delta v$ of (4.2), are almost the standard parameters of elliptic function theory: $g_2 = 4 \delta u$ and $g_3 = 4 \delta v$. The small torus becomes

$$w^2 = 4x^3 - g_2 x - g_3.$$  

(4.13)

Another pair of parameters we can use are the two periods of the holomorphic form $dx/w$, to be called $\omega$ and $\omega_D$. * Their ratio is $\tau = \omega_D / \omega$, while their overall scale is related to

* In many references, the periods are $2\omega$ and $2\omega_D$. 

23
\( \epsilon \) as \( \epsilon^{-1/2} \). The short periods \( a_1 \) and \( a_1^D \) are the periods of the form \( \tilde{\lambda} = w \, dx \). The \( \mathbb{Z}_3 \) symmetry is \((\omega, \omega_D) \rightarrow (\omega_D, -\omega - \omega_D) \) and acts the same way on \((a_1, a_1^D)\). The relation between \((g_2, g_3)\) and \((\omega, \omega_D)\) is standard:

\[
\frac{g_2}{60} = \sum_{m,n} \frac{1}{(m\omega + n\omega_D)^4} = \frac{\pi^4}{45 \omega^4} (1 + 240q + \ldots) \tag{4.14}
\]

\[
\frac{g_3}{140} = \sum_{m,n} \frac{1}{(m\omega + n\omega_D)^6} = \frac{2\pi^6}{35 \cdot 27 \omega^6} (1 - 504q + \ldots).
\]

Using properties of these elliptic functions it is shown in the Appendix that

\[ a_1 = -\frac{\pi i}{5} \frac{\partial g_2}{\partial \omega_D}, \quad a_1^D = \frac{\pi i}{5} \frac{\partial g_2}{\partial \omega}, \quad \omega_D a_1 - \omega a_1^D = \frac{4\pi i}{5} g_2. \tag{4.15} \]

The degeneration \( \tau \rightarrow i\infty \) takes

\[ a_1 \sim \frac{128 \pi^6}{\omega^5} e^{2\pi i \tau} \rightarrow 0, \quad a_1^D \rightarrow -i \frac{16 \pi^5}{15 \omega^5}, \tag{4.16} \]

reproducing the result (4.12).

We now derive the prepotential \( F(a_1, a_2) \). A long period \( a_2 \) depends only weakly on the degeneration parameters. It can be calculated by expanding \( \lambda \) in \( \delta u \) and \( \delta v \), and it will depend analytically on them:

\[ a_2 = \hat{a}_2 + C \frac{\delta u}{\Lambda} + \mathcal{O} \left( \frac{\delta v}{\Lambda^2} \right) + \mathcal{O} \left( \frac{\delta u^2}{\Lambda^3} \right), \tag{4.17} \]

where \( \hat{a}_2 \sim \Lambda \) is the value of the long period at the \( \mathbb{Z}_3 \) point, and \( C \) is some calculable constant. If we take \( \delta u \sim \epsilon^2 \) and \( \delta v \sim \epsilon^3 \), the \( \delta v \) dependence is subleading, so we can trade \( a_2 \) for \( g_2 = 4\delta u \) by writing \( g_2 = (4/C)\Lambda(a_2 - \hat{a}_2) \). A small variation of \( a_2 \) translates into a large variation of \( g_2 \) and thus of \( \rho \) and \( \tau \): \( \partial \tau / \partial a_2 \sim \Lambda / \epsilon^2 \).

The results (4.15) implicitly define the prepotential \( F(a_1, g_2) \) and the functions \( \tau(a_1, g_2) \) and \( a_1^D(a_1, g_2) \) appearing in the effective Lagrangian. A more explicit expression would be too complicated to be very illuminating, and it is better to think in terms of the picture in Fig. 9. The limiting behavior of \( F \) as \( a_1 \rightarrow 0 \) is simple: to reproduce \( \partial F / \partial a_1 = a_1^D \),

\[ F(a_1, a_2) \rightarrow -i \frac{(3 \cdot 64)^{1/4}}{5} a_1 g_2^{5/4} \propto a_1 (a_2 - \hat{a}_2)^{5/4}. \tag{4.18} \]
The non-trivial exponent is associated with the scaling $m \sim e^{5/2}/\Lambda^{3/2}$ derived earlier. (Note that this non-analyticity is not directly reflected in the monodromy—the non-trivial monodromy visible in this limit is $a_1 \to e^{2\pi i}a_1$, while in the limit $g_2 \to 0$ this asymptotic form is not valid.)

4.2. Stability of BPS states

As discussed in [2], BPS states become marginally stable on lines $\text{Im}a_D^1/a_1 = 0$. We now prove a result needed for section 5: for small $\epsilon$, this line is a simple closed curve in the $\rho$ plane, passing through each cusp, separating $|\rho| >> 1$ from $|\rho| << 1$, and $a_D^1/a_1$ can take any real value.

$a_D^1/a_1$ transforms under $SL(2,\mathbb{Z})$ in the same way as $\tau$. The $\rho$ plane can be mapped to the region $0 \leq \text{Re} \tau \leq 1$, $|\tau - 1/2| > \frac{1}{2}$. Its image in the $a_D^1/a_1$ plane is the region $R'$ shown in Fig. 10, and the dashed line in the region $R$ is the preimage of $\text{Im}a_D^1/a_1 = 0$.

![Fig. 10: The complex $\tau$ and $a_D^1/a_1$ planes. The modular domains mapped onto the $\rho$ plane are shown. The dashed curve is the image of the $\text{Im}a_D^1/a_1 = 0$ curve in the $\tau$ plane.](image)

This can be seen as follows. First, for large $\text{Im} \tau$, $a_D^1/a_1 = \tau + (1/120\pi)e^{2\pi i \text{Im} \tau}e^{i\pi(3/2 - \text{Re} \tau)}$ and a line $0 \leq \text{Re} \tau \leq 1$ with $\text{Im} \tau$ fixed sweeps out a large circle in the $a_D^1/a_1$ plane. The images of $\tau = 0$ and $\tau = 1$ are known, and from the expression for $a_D^1/a_1$ it is clear that the outer lines run parallel to the imaginary axis.
We then observe that if two points in the $\tau$ plane are related by $SL(2,\mathbb{Z})$ as $\tau_1 = g(\tau_2)$, their images in the $a_1^D/a_1$ plane will have the same relation. $\tau = i$ is a fixed point of $z \to -1/z$, so its image is $a_1^D/a_1 = -i$. By applying $z \to -1/(z - 1)$ we get $\tau = \frac{1}{2}(1 + i)$, so its image is $a_1^D/a_1 = \frac{1}{2}(1 - i)$. Finally, the quarter arcs $\tau = 0$ to $\tau = \frac{1}{2}(1 + i)$ and $\tau = 1$ back to $\tau = \frac{1}{2}(1 + i)$ and their images are exchanged by the $SL(2,\mathbb{Z})$ transformation $z \to \frac{z - 1}{2z - 1}$, and related by $\text{Re} \tau \to 1 - \text{Re} \tau$, which determines them.

4.3. Breaking to $\mathcal{N} = 1$

We now consider what happens to the $\mathcal{N} = 2$ $SU(3)$ gauge theory when we add terms to the microscopic superpotential explicitly breaking $\mathcal{N} = 2$ to $\mathcal{N} = 1$ supersymmetry. We will not use these results in an essential way, but it is interesting to see that the resulting $\mathcal{N} = 1$ theory will have ground states near the $\mathbb{Z}_3$ point, and that the pure $\text{Tr} \varphi^3$ superpotential makes the $\mathbb{Z}_3$ point itself a ground state.

Near a point in moduli space where two or fewer mutually local dyon hypermultiplets are massless we can, by a duality transformation on the low energy gauge fields, choose them to be separately electrically charged with respect to the two $U(1)$'s. Denote by $A_i$, $i = 1, 2$ the $\mathcal{N} = 1$ chiral superfield parts of the two $\mathcal{N} = 2$ $U(1)$ gauge multiplets, and by $a_i$ the vevs of the lowest components of $A_i$. Then locally the $a_i$ are coordinates on the moduli space which vanish where the dyon charged with respect to their $U(1)$ is massless. In terms of the $\mathcal{N} = 1$ chiral superfields $M_i, \tilde{M}_i$ which form the dyon hypermultiplets, the $\mathcal{N} = 2$ superpotential becomes

$$W_0 = \sqrt{2} \sum_{i=1}^2 A_i M_i \tilde{M}_i. \quad (4.19)$$

In the microscopic superpotential we can add the two renormalizable terms $(\mu/2)\text{tr} \Phi^2 + (\nu/3)\text{tr} \Phi^3$, which break $\mathcal{N} = 2$ to $\mathcal{N} = 1$. For small $\mu$ and $\nu$, the superpotential in the low-energy theory is then

$$W = W_0 + \mu U + \nu V. \quad (4.20)$$

where $U, V$ are the superfields corresponding to $\text{tr} \Phi^2$ and $\text{tr} \Phi^3$ in the low energy theory; their first components have the expectation values $\langle u \rangle = \frac{1}{2} \langle \text{tr} \varphi^2 \rangle$ and $\langle v \rangle = \frac{1}{3} \langle \text{tr} \varphi^3 \rangle$. Using
the non-renormalization theorem of [18], an argument like one in [2] shows that (4.20) is
the exact low-energy superpotential. Since \(u\) and \(v\) are good global coordinates on moduli
space, it is useful to take them as our basic chiral fields and consider \(A_i(U, V)\) as functions
of them.

The vanishing of the \(D\)-terms imply \(|m_i| = |\tilde{m}_i|\), while setting \(dW = 0\) gives the
vacuum equations

\[
-\frac{\mu}{\sqrt{2}} = \frac{\partial a_1}{\partial u} m_1 \tilde{m}_1 + \frac{\partial a_2}{\partial u} m_2 \tilde{m}_2, \\
-\frac{\nu}{\sqrt{2}} = \frac{\partial a_1}{\partial v} m_1 \tilde{m}_1 + \frac{\partial a_2}{\partial v} m_2 \tilde{m}_2, \tag{4.21}
\]

and

\[
a_1 m_1 = a_1 \tilde{m}_1 = 0, \\
\tag{4.22} \\
a_2 m_2 = a_2 \tilde{m}_2 = 0.
\]

Here we have denoted by lower-case letters the vevs of the first components of the corre-
sponding upper-case superfields.

At a point in moduli space where no dyons are massless, both \(a_i\) are non-zero, so by
(4.22) \(m_i = \tilde{m}_i = 0\). Then (4.21) has a solution only if \(\mu = \nu = 0\). Thus we learn that the
generic \(N = 2\) vacuum is lifted by the superpotential.

Now consider the \(\mathbb{Z}_2\) points in moduli space where two mutually local dyons are
massless. At these points \(a_1 = a_2 = 0\), so the \(m_i\) are unconstrained by (4.22). For any \(\mu, \nu\),
(4.21) can be solved by adjusting \(m_i \tilde{m}_i\) appropriately, since the \(a_i\) are non-degenerate
coordinates at these points. Up to gauge transformations this is a single solution, describing
a vacuum with a magnetic Higgs mechanism in both \(U(1)\) factors. These \(N = 1\) vacua
persist for all values of the bare couplings \(\mu\) and \(\nu\).

The interesting case is at a point with just one massless dyon, say \(M_1, \tilde{M}_1\). In
terms of local coordinates on the \(N = 2\) moduli space, this occurs along the one complex
dimensional curve \(a_1 = 0\), but \(a_2 \neq 0\). In terms of the global coordinates \(u, v\), this curve is
one of the single dyon singularities \(\Delta(Q_{\pm}) = 0\) discussed in Section 2. A simplified picture
of these curves is shown in Fig. 11. Eq. (4.22) implies \(m_2 = 0\), and so (4.21) has a solution if

\[
\frac{\mu}{\nu} = \frac{(\partial a_1/\partial u)}{(\partial a_1/\partial v)}, \tag{4.23}
\]
since $m_1$ can be adjusted freely. It is easy to see qualitatively where this condition has solutions. The components in the $u, v$ coordinate system of the normal vector to the massless dyon curve $a_1 = 0$ are $(\partial a_1/\partial u, \partial a_1/\partial v)$. If $\nu = 0$, so that there is only a $\text{tr} \Phi^2$ breaking term, then a solution exists only at a point where $\partial a_1/\partial v = 0$. But, from Fig. 11 it is apparent* that the $v$-component of the normal vector to any of the single-dyon curves vanishes only at infinity, and thus there are no new $\mathcal{N} = 1$ vacua (in addition to the $\mathbb{Z}_2$ points, which always remain vacua). Now, if we turn on a small $\text{tr} \Phi^3$ term, $|\mu/\nu| \gg \Lambda$, then the solutions of (4.23) will move in from infinity along the single-dyon curves. This is shown in Fig. 11: decreasing $|\mu/\nu|$ corresponds to moving the dashed line towards $u = 0$; its intersections with the single-dyon curves are the new $\mathcal{N} = 1$ vacua. Under the discrete global $\mathbb{Z}_6$ $R$-symmetry, $\mu/\nu \rightarrow e^{i\pi/3} \mu/\nu$ when $u \rightarrow e^{2\pi i/3} u$ and $v \rightarrow -v$. Thus, changing the sign of $\mu/\nu$ will pick out two different $\mathcal{N} = 1$ vacua related to the first two by $v \rightarrow -v$ with their $u$ coordinates the same.

![Fig. 11](image)

Fig. 11: A 2-dimensional section of the $SU(3)$ moduli space, showing the two massless-dyon curves. The two cusps are the $\mathbb{Z}_3$ points, and their intersection is one of the $\mathbb{Z}_2$ points. The dashed $u =$-constant line is determined by the ratio of the $\mathcal{N} = 2$-breaking parameters $\mu/\nu$. The open circles denote points which remain $\mathcal{N} = 1$ vacua upon breaking with those parameters.

Thus, for generic $\mu/\nu$ we find a total of five $\mathcal{N} = 1$ vacua (three of which are shown in Fig. 11). Three are the completely Higgsed $\mathbb{Z}_2$ points already discussed, while the other two are vacua in which one $U(1)$ factor is magnetically Higgsed, while the other remains

---

* Actually, Fig. 11 suppresses the fact that $u$, $v$, and $\mu/\nu$ are really complex; however, it is not hard to see that the complex structure ensures that the conclusions of this two-real-dimensional reasoning are correct.
unHiggsed since there are no light particles charged with respect to it. We will refer to these latter two vacua as the “half-Higgsed” vacua.

There are eight special values of $\mu/\nu$ at which this generic situation no longer holds. The first is $\mu/\nu = \infty$, discussed above, where only the three $\mathbb{Z}_2$ vacua are not lifted. The next six are $\mu/\nu = e^{i\pi k/3}\Lambda$, $k = 1, \ldots, 6$, where one of the half-Higgsed vacua coalesces with the $\mathbb{Z}_2$ vacuum at $v = 0, u = e^{2i\pi k/3}\Lambda^2$. It is easy to see from the explicit computations of $\mathbb{F}$ near the $\mathbb{Z}_2$ points that at, say, the $v = 0, u = e^{2i\pi k/3}\Lambda^2$ vacuum
\[ \frac{\partial a_1}{\partial u} = C \cdot \frac{e^{1/2}\Lambda^{-3/2}}, \quad \frac{\partial a_1}{\partial v} = C \cdot \frac{e^{-1/2}\Lambda^{-3/2}}, \quad (4.24) \]
for some constant $C$. So as one approaches the $\mathbb{Z}_3$ point $\epsilon \to 0$ indeed implies $\partial a_1/\partial u \to 0$.

The fact that $\partial a_1/\partial v \to \infty$ as $\epsilon^{-1/2}$ implies that the vev of the lowest component of the monopole hypermultiplet scales as $M_1/\Lambda \sim \nu^{1/2}(\epsilon/\Lambda)^{1/4}$ near the $\mathbb{Z}_3$ point. The $U(1)$ factor with respect to which the light hypermultiplets are charged has a gap in the $\mathcal{N} = 1$ vacuum which vanishes as it approaches the $\mathbb{Z}_3$ point. Thus the $\mathcal{N} = 1 \mathbb{Z}_3$ vacua with a tr$\phi^3$ superpotential may be non-trivial fixed points.

5. Physical Interpretations of the $\mathbb{Z}_3$ Vacua

First, we remind the reader that we have only the low-energy effective Lagrangian, and a certain amount of inference will be necessary. Everywhere except exactly at the $\mathbb{Z}_3$
point, the massless degrees of freedom are two $U(1)$ gauge multiplets. The $\mathbb{Z}_3$ point itself is somewhat ambiguous—as we saw, we can keep $\tau$ at any fixed value as we take the limit $\epsilon \to 0$.

Near the $\mathbb{Z}_3$ point, there are two basic scales in the theory. Most of the particles have mass $O(\Lambda)$, as is generic in the strong coupling regime. In particular, from (2.24), all particles with zero magnetic charge have mass $O(\Lambda)$, which includes the original charged $SU(3)$ gauge bosons.

The masses of the light hypermultiplets set another scale. Generically there are three hypermultiplets with mutually non-local charges under a single $U(1)$, with comparable masses $m_i \sim m$. For $m << \Lambda$ the kinetic term is almost diagonal and at scales below $\Lambda$ the other degrees of freedom decouple. Limits exist in which one of the three hypermultiplets is much lighter than the other two, e.g. $m_1 << m_2 \sim m_3 \sim m$, and then the low energy $U(1)$ coupling depends on $m_1$ in just the way we expect for $U(1)$ gauge theory containing only that particle at scales below $m$. There is a complete symmetry between the three hypermultiplets.

Very strikingly, the low energy coupling was independent of the separation of scales $m/\Lambda$. We infer that the gauge coupling does not run below the scale $\Lambda$. The dependence we did find was on ratios of particle masses, and the simplest interpretation of this is that the gauge coupling does not run above the heaviest particle mass. Thus we conclude that the theory is essentially an RG fixed point between scales $\Lambda$ and $m$. (The qualifier “essentially” allows for possible relevant operators associated with the scale $m$.) No such fixed point exists for $U(1)$ gauge theory with ordinary charged matter—the mutually non-local charged matter must play an essential role.

Other interpretations are conceivable if there is additional physics at an intermediate scale $\mu$, for example the beta function might be negative above $\mu$ and positive below $\mu$. Now we know that BPS saturated states do not appear at intermediate scales, but it is not clear to us how to disprove the hypothesis that non-BPS states might be associated with a scale such as the $\epsilon$ of section 4, satisfying $m \sim \epsilon^{5/2}/\Lambda^{3/2}$. This would also be a very novel field theory, and we see no evidence for the additional complications of this scenario. Rather than evidence for an intermediate scale, we will later interpret appearances of $\epsilon$ as
the consequence of non-trivial anomalous dimensions in the fixed point theory.

In the limit $m \to 0$, the theory becomes a non-trivial RG fixed point theory. Although the coupling $\tau$ of the low-energy theory is adjustable, this is the coupling below the scale $m$, not the fixed point coupling. We can find the fixed point coupling by considering the special case $\rho = 0$ where all three particles have the same mass. Since they decouple in a symmetric way, the coupling should be the same above and below this scale. Thus the fixed point is at strong coupling, $\tau_c = e^{2\pi i/3}$.

One possibility is that it is a non-trivial fixed point involving precisely these three particles. Although each separately would produce a beta function, their effects cancel out. Another possibility is that additional particles our analysis did not detect cancel the beta function. Finally, it is conceivable that somehow none of the three particles contribute to the beta function above the scale $m$.

Let us briefly discuss the last possibility. It is familiar that particles stop contributing to the beta function at energies below their mass, but how can a particle not contribute above an energy $E$? Now there is a well-known case of a charged ‘particle’ in gauge theory which does not affect the beta function above an energy $E$. It is the conventional ’t Hooft-Polyakov monopole, which at weak electric coupling is generally taken not to affect the beta function at all. Since its magnetic gauge coupling is large, we should explain why at higher energies than its mass $m_W/g^2$, it does not produce a one-loop beta function.

The explanation is familiar. The monopole has a size of $O(1/m_W)$, and has small matrix elements with local operators on shorter length scales. This is the sense in which the monopole decouples above the energy $m_W$.

Could it be that all three particles in the present theory are extended objects, with sizes (at least) $1/m$, and thus do not contribute to the beta function above this scale? We would have a fixed point theory between the scales $\Lambda$ and $m$ but an effectively trivial one. Although this is a consistent interpretation of the information given to us by the effective theory, it does not seem very likely to us. The charged particles were monopoles and dyons of the original $SU(3)$ theory and even in the quantum theory, a particle with magnetic charge must contain some core with unbroken non-abelian symmetry. One expects the size of the particle to be $1/\Lambda$, the scale set by the mass of the $SU(3)$ gauge bosons. This is
clear semiclassically and a non-trivial check of it at strong coupling was discussed in \[5\].

Another way to suppress the beta function would be for the three particles to form some sort of confined neutral bound state below the scale \(\Lambda\). However, it is very hard to see how a single charged particle could be liberated at scales below \(m\). Nevertheless we mention these possibilities for completeness.

What about the second possibility, that we have not yet identified all the massless particles? Perhaps the most interesting version of this idea begins by noting the similarity of this point with the “non-abelian Coulomb” points found in the moduli space of \(\mathcal{N} = 1\) supersymmetric gauge theories in \([11,12]\). The prototypical example of such a point is the point \(\langle \phi \rangle = 0\) in \(\mathcal{N} = 4\), \(SU(2)\) super Yang-Mills theory, with unbroken non-abelian gauge symmetry. The classical central charge formula is valid with \(a = \phi\) and \(a_D = \tau \phi\), so both the charged gauge bosons and the monopoles become massless at this point. The beta function is zero at all scales, and the gauge coupling is freely adjustable.

Non-trivial fixed points at unique critical couplings \(\tau^*\) are believed to exist \([1]\) in \(\mathcal{N} = 1\) supersymmetric QCD with \(3N_c/2 < N_f < 3N_c\) fundamental flavors, or with an adjoint chiral superfield and \(2N_c/3 < N_f < 2N_c\) flavors \([19]\). These theories exhibit dual descriptions in terms of (different) light magnetic degrees of freedom. These degrees of freedom are presumed to be solitons in the original electric variables and thus both electrically and magnetically charged light states are present. A particularly suggestive analogy can be drawn to \(\mathcal{N} = 1\), \(SO(3)\) gauge theory with two flavors \([12,20]\) which can be described using fundamental electron, monopole, or dyonic variables.*

The non-trivial fixed points are perhaps more similar to what we found, but the main point seems to be that all of these fixed point theories contain non-Abelian gauge bosons which produce a negative contribution to the beta function.

The known models also contain additional matter—at least two doublet hypermultiplets to realize the model of \([19]\). This already leads to severe difficulties with this identification, as it implies that the model has additional global symmetry, and additional ‘Higgs branches’ of the moduli space reached by turning on large squark vevs, all of which should have been visible in the semiclassical limit.* One might still imagine that we have

* We thank N. Seiberg for this example and the argument below.
discovered a non-abelian Coulomb phase without additional matter.

We now argue that there are no massless non-abelian gauge bosons at the $\mathbb{Z}_3$ point. Now the non-abelian gauge bosons as well as the additional matter we would need are all BPS saturated states. By moving away from the $\mathbb{Z}_3$ point in the $\mathcal{N} = 2$ moduli space, we can make the generic BPS state massive. On the other hand, we will see that for every possible charged state, there is a line we can move on which keeps only it (and states with multiples of its charge) massless. The resulting low energy theory is a standard $U(1)$ gauge theory with mutually local charges, and the charged spectrum will be reflected in the low energy gauge coupling by standard field theoretic considerations. Thus, from the effective Lagrangian we can make strong statements about the existence of charged BPS particles.

The minimal test for a candidate ‘$W$ boson’ is that it have charge 2 in some basis. If we were to find a candidate, we would then need to check that it is in a vector multiplet, but this will not be necessary. There are two possibilities; in the basis in which the three known hypermultiplets have charge $(1\ 0)$, $(0\ 1)$ and $(-1\ -1)$, the first possibility is the bound state of two monopoles $(2\ 0)$ (or its $\mathbb{Z}_3$ images), while the second possibility is a more complicated bound state, for example $(2\ 4)$.

Consider the first possibility, e.g. the state $(2\ 0)$. This is a particle which is believed not to exist semiclassically; certainly for $SU(2)$ the multi-monopole moduli space is known to be connected [21] and there is no distinct charge $|h| > 1$ monopole solution, nor is there such a state in the quantized two-monopole system. However we do not know a proof for the $SU(3)$ theory at hand, and we do not want to rely on semiclassical results, so we will argue as follows. If the particle existed near the $\mathbb{Z}_3$ point, we could follow it out along a trajectory near the line on which the $(1\ 0)$ state was massless, and it would give an additional logarithmic contribution to the beta function everywhere along that line, which is not present. Thus this particle does not exist. Indeed we could follow the line all the way to a $\mathbb{Z}_2$ point, with no signal from the effective Lagrangian of any instability, so the existence of the particle would probably invalidate the rather successful physical picture of the $\mathcal{N} = 1$ theory given in [2][3][4].

The other possibility is a state like $(2\ 4)$. If it were possible to find a state which became massless only at the $\mathbb{Z}_3$ point itself, it would be available to cancel the beta
function between $\Lambda$ and $m$, but the previous argument would not apply.

This is not possible. A state with charges $(m,n)$ will become massless along the line $ma_1 + na_D = 0$ or equivalently $a_D^1/a_1 = -m/n$. In section 4, we saw that there exist trajectories out of the $\mathbb{Z}_3$ point on which $a_D^1/a_1$ takes any fixed real value, with fixed $\rho$ and $\epsilon$ variable. Along this line, the massless charged spectrum of the low energy theory is again local and if these states existed they would have left a direct signature in the effective Lagrangian. We conclude that only the three hypermultiplets we already identified exist.

This argument from the singularities of the effective Lagrangian is quite general. For example, it applies to the $SU(2)$ solutions of [22] and shows that for $N_f \leq 2$, no BPS state with magnetic charge $h \geq 2$ is stable anywhere in moduli space, while for $N_f = 3$, only the $(2,1)$ state and its images $(2,2k+1)$ exist.

6. $U(1)$ Gauge Theory with Mutually Non-local Charges

Both the evidence from the effective Lagrangian, and consideration of alternate interpretations, led us to conclude that the low energy theory of the $\mathbb{Z}_3$ point is a field theory of a truly novel type, a non-trivial interacting $\mathcal{N} = 2$ superconformal theory involving two $U(1)$ gauge multiplets and three hypermultiplets with mutually non-local charges under one of the $U(1)$’s. We now take the limit $\Lambda \to \infty$, after which only these degrees of freedom remain. This is the degeneration limit of the quantum surface and the $U(1)^2$ effective Lagrangian was described in section 4.

The resulting theory still has a two complex dimensional space of vacua. Generically, all the hypermultiplets are massive, and there should be no difficulty in making a particle interpretation of the theory. At energies where pair creation is unimportant, the known quantum mechanical formulations (for example [11]) should apply. By tuning the mass of one hypermultiplet to zero, one produces massless QED with additional massive monopoles and dyons, which again should not be much more difficult to treat than massless QED.

By tuning to the $\mathbb{Z}_3$ point, or adding the superpotential $\text{Tr} \phi^3$, we produce a superconformal theory. Whether a particle interpretation can be made for it is not at all clear. The effective Lagrangian gives only limited insight into the physics, because the fixed point is
strongly coupled. Clearly an important problem for future work is to find a more direct treatment of this theory. The following are some observations and speculations in this direction.

Let us try to write a bare Lagrangian at the scale $\Lambda$ which defines the fixed point theory and its relevant perturbations. It will certainly contain the hypermultiplets and the non-trivial $U(1)$.

It is not as obvious whether it must contain the second $U(1)$ under which the hypermultiplets are neutral. In the $\mathcal{N} = 1$ theory with a superpotential, the vacuum is determined as discussed in section 4, and it would appear that one requires both flat directions and thus both $U(1)$’s to describe this. In the $\mathcal{N} = 2$ theory the second $U(1)$ decouples in the following sense. First, its vector potential and fermions might couple through off-diagonal gauge kinetic terms. From (4.8), the corresponding terms in the effective Lagrangian were higher dimension operators with the standard suppression by inverse powers of the cutoff, $\sim (a_1/\Lambda)W^1W^2$, and it is very plausible that this is also true at the scale $\Lambda$, so that the vector potential and fermions decouple as $\Lambda \to \infty$.

There is also explicit dependence of $\tau_{11}$ on the scalar $a_2$. From (4.18), $\tau_{11}$ depends on $a_2$ as a function of $g_2^{5/4}/a_1\Lambda^{3/2} \sim (a_2 - \hat{a}_2)^{5/4}/a_1\Lambda^{1/4}$ and at the scale $m \sim a_1$ these couplings are suppressed by powers of $((a_2 - \hat{a}_2)/\Lambda)^{1/4} \sim (a_1/\Lambda)^{1/5}$. Essentially, the leading operator coupling the two sectors in the effective Lagrangian, $((a_2 - \hat{a}_2)/\Lambda)^{1/4}(\partial a_1)^2$, is irrelevant.

Thus it appears that we can drop the second $U(1)$, but we still need to allow varying the expectation value of $a_2$. We could reproduce this if the fixed point theory has a relevant perturbation $(a_2 - \hat{a}_2)O_2$ producing the flow to $\mathcal{N} = 2$ supersymmetric QED. This would make sense if $O_2$ has dimension $\Delta > 3$, so that the expectation value $(a_2 - \hat{a}_2)O_2$ is relevant but the fluctuation $\delta a_2 O_2$ is irrelevant. (Such an operator, irrelevant in the UV limit of a flow but becoming relevant in the IR, is referred to as a ‘dangerous irrelevant operator’ in critical phenomena.) The dependence of the low-energy Lagrangian on $(a_2 - \hat{a}_2)^{5/4}$ would be explained if $O_2$ had dimension $\Delta = 3 + 1/5$.

A similar discussion can be made for the $N$-fold critical point present in $SU(N)$ gauge theory, and leads to the conclusion that the decoupled $U(1)$’s are associated with a series
of irrelevant operators with dimension \(5 - 2n/(N + 2), 2 \leq n < N/2 + 1\).

To couple to all three hypermultiplets, we need a Lagrangian including both the gauge field and its dual. Such a Lagrangian has been written by Schwarz and Sen \([7]\); however Lorentz invariance and \(\mathcal{N} = 2\) supersymmetry are not manifest. Let us assume such Lagrangians exist but for now not use specific forms or symmetry properties. Indeed, we do not know a priori what is an appropriate gauge Lagrangian for this strongly coupled theory. Below the scale \(m\), the gauge field fluctuations are of course controlled by the usual quadratic kinetic term, but to emphasize our uncertainty about this point in the fixed point theory, we allow an additional unknown term \(S_0\) in the action.

We write

\[
S = S_0(V, V_D, A, A_D) + \frac{\tau}{4\pi} S_{\text{free}}(V, V_D, A, A_D) + (\langle a_2 \rangle - \hat{a}_2)O_2 \\
+ \int d^4x d^4\theta \ E^+ e^V E + M^+ e^{V_D} M + D^+ e^{V + V_D} D + \text{charge conj.} \\
+ \sqrt{2} \int d^4x d^2\theta \ EA\tilde{E} + MA_D\tilde{M} + D(A + A_D)\tilde{D} + \text{h.c..}
\]  

(6.1)

The fields \(A_D\) and \(A\) are not independent. We know the relation \(A_D = \partial F(A, A_2)/\partial A\) in the effective Lagrangian, which we interpret by replacing \(A_2\) with the vev of its scalar component. One test of the bare Lagrangian would be to reproduce this relation in the low energy limit.

Given a particular \(S_0\), or even assuming \(S_0 = 0\), a serious obstacle to using this directly is that the fixed point is at strong coupling. Nevertheless, let us see what we can do. The simplest check would be to find a zero of the beta function. There is a simple ansatz which produces the correct fixed point coupling, illustrates what is going on, and might be correct. It is to compute the contribution of each hypermultiplet separately to the beta function of its ‘natural’ gauge coupling, and then use \(SL(2, \mathbb{Z})\) to express the answers in terms of a single coupling.

By \(\mathcal{N} = 2\) supersymmetry, the only perturbative contribution to the beta function will be at one loop. In \(D = 4\) \(U(1)\) gauge theory with a single hypermultiplet, one does not expect non-perturbative contributions. This is the standard one-loop renormalization

\[
\Delta \mathcal{L}_{\text{eff}} = \frac{i}{\pi} g_i^2 \log \Lambda_0^2 \left( \int d^4\theta \ A_i A_i^+ + \int d^2\theta \ W_i^2 + \text{c.c.} \right)
\]  

(6.2)
which does not depend on the (unknown) gauge Lagrangian.

Let us then take as the beta function due to the electron

$$\frac{\partial}{\partial \log \mu} \tau = -\frac{i}{2\pi}. \quad (6.3)$$

A theory with a single hypermultiplet with charge \((q_m, q_e)\) is just as easy to deal with, by using \(SL(2, \mathbb{Z})\) to write the gauge action in terms of \(V_{(q_m, q_e)} = q_m V_D + q_e V\). This will transform the original electric \(\tau\) into

$$\tau_{(q_m, q_e)} = \frac{1}{\gcd(q_e, q_m)} \frac{a\tau + b}{q_m \tau + q_e} \quad (6.4)$$

with \(a\) and \(b\) integers chosen to make \(aq_e - bq_m = \gcd(q_e, q_m)\). Transforming back, it contributes the electric beta function

$$\frac{\partial}{\partial \log \mu} \tau = \frac{\partial \tau_{(0,1)}}{\partial \tau_{(q_m, q_e)}} \frac{\partial}{\partial \log \mu} \tau_{(q_m, q_e)}$$

$$= -\frac{i}{2\pi} (q_m \tau + q_e)^2. \quad (6.5)$$

At this point the main assumption is duality in the quantum theory. In general, magnetically charged hypermultiplets make the electric coupling relevant, as was observed in the context of the dual \(U(1)\) Lagrangian of [2]. An interesting feature of the result is that with magnetically charged hypermultiplets, the flow depends on and can change the real part of \(\tau\). Although normally \(U(1)\) gauge theory in \(D = 4\) is unaffected by the \(\theta\) angle, theories containing electric and magnetic charges can be affected.

A very natural ansatz for the total beta function is simply to add the individual electric beta functions. The main justification we will give for this is the observation that the duality transforms of \((\ref{eq:6.2})\) are expressed in terms of \(W, W_D, A\) and \(A_D\), which are all locally related operators, unlike the vector potentials. Thus, despite the subtleties associated with mutually non-local charges, we can make sense of the RG.

We thus find the condition for a fixed point:

$$\sum_i (q_{mi} \tau_c + q_{ei})^2 = 0. \quad (6.6)$$

For our spectrum we have \(1 + \tau_c^2 + (\tau_c + 1)^2 = 0\) implying

$$\tau_c = e^{2\pi i/3}, \quad (6.7)$$
so this simple ansatz produces the correct fixed point coupling. Now this is not really convincing evidence that the beta function is exact; it might be that the corrections also cancel. Indeed, the $\mathbb{Z}_3$ symmetry of the spectrum essentially guarantees that there will be a fixed point at this $\tau_c$. The beta function will satisfy $\beta(g(\tau)) = g(\beta(\tau))$ for any symmetry $g \in \text{SL}(2, \mathbb{Z})$ of the quantum theory, and thus fixed points of the symmetry will be fixed points of the RG.

Another interesting property of this beta function is that its fixed point is attracting. There is an even simpler fixed point theory which we will use to demonstrate this—the theory containing only an electron and a monopole. Now since we do not have a realization of it, we cannot be sure that this theory is consistent. Perhaps consistency conditions not yet known to us require three hypermultiplets. In any case, this calculation of its beta function does make sense, and produces $\tau_c = i$. Then, expanding $\tau = i + \delta$, for small $\delta$ the flow becomes $d\delta/ds = -\delta/\pi$. The flow in the three particle model around $\tau_{c3}$ is similar, with $d\delta/ds = -(\sqrt{3}/\pi)\delta$.

The meaning of the result is that $S_{\text{free}}$ is an irrelevant operator. If we believe the one-loop result is exact, we find its anomalous dimension (in the three-particle theory) to be $\sqrt{3}/\pi$. Now we already saw a non-trivial dimension for the operator $O_2$, which we inferred from effective field theory results such as $\langle 4.18 \rangle$, and it was a rational number. We consider the non-rationality of the anomalous dimension we found for $S_{\text{free}}$ to be some evidence against its exactness – perhaps non-perturbative effects are present, or perhaps $S_0$ is important.

Whether or not this anomalous dimension is exact, it is very suggestive that it is positive. In a unitary conformal theory, the anomalous dimension of a scalar field is required to be non-negative, and zero anomalous dimension implies that it is a free field $\langle 23 \rangle$. Thus this result is consistent with the non-trivial nature of the fixed point.

Since this is a superconformal theory, there must be an unbroken $U(1)_R$ symmetry, and unlike the models of $\langle 1, 19, 24 \rangle$ there is no obvious candidate for this among the original symmetries. A novel feature following from the generation of massless solitons, is the generation of new chiral symmetries. Indeed, it would appear that each massless hypermultiplet will come with its own $U(1)_L \times U(1)_R$ fermion number symmetries. We expect the
chiral symmetry to be anomalous, and duality transforming the standard chiral anomaly for electrically charged hypermultiplets, the monopole also has the standard anomaly, but dyons will have terms such as

$$\partial^\mu J_{\mu \phi} = \ldots + q_e \cdot q_m (E^2 - B^2).$$  \hspace{1cm} (6.8)

Although it may seem difficult to cancel anomalies such as $\text{(6.8)}$, we have already seen it implicitly in the statement that summing the flows $\text{(6.2)}$ produces a fixed point.

A toy model for some of these phenomena would be an analogous theory in two dimensions, with matter couplings to a scalar field $\phi$ and its dual $d\phi = \ast d\tilde{\phi}$ producing a beta function for each. Of course the dimensional reduction of the present theory would be such a model, but simpler possibilities might exist. It would be interesting to study the topologically twisted form of the $D = 4$ theory as well.

7. Conclusions

We have given strong evidence for the existence of a sensible, $D = 4$, $\mathcal{N} = 2$ supersymmetric $U(1)$ gauge theory containing an electron, a monopole and a dyon hypermultiplet, as a special vacuum of $SU(3)$ gauge theory. We believe this is the first strong evidence that Dirac’s original conception of gauge theory containing fundamental electrons and monopoles can be realized in a fully consistent local relativistic theory.

Furthermore, the theory at the $\mathbb{Z}_3$ point may well be the simplest non-trivial $D = 4$, $\mathcal{N} = 2$ superconformal theory. We proposed a general mechanism to produce fixed points in theories with mutually non-local charges, and saw that it fit the data from the effective theory. We identified non-trivial critical exponents in the theory.

Clearly the main problem for future research is to construct and work with a direct definition of the theory. There is a series of generalizations at special vacua of $SU(N)$ gauge theory to study as well. We have no doubt that this will shed much light on $D = 4$ superconformal field theory, and field theory in general.

Appendix A. Calculation with Elliptic Functions

The relation between \((g_2, g_3)\) and \((\omega, \omega_D)\) is standard \[17\]. A convenient normalization for the \((g_2, g_3)\) functions is

\[
g_2 = \frac{4\pi^4}{3\omega^4} E_4(\tau), \quad g_3 = \frac{8\pi^6}{27\omega^6} E_6(\tau),
\]

(A.1)

with \(q = e^{2\pi i \tau}\). These are modular functions in \(\tau\) satisfying \(E_k(-1/\tau) = \tau^{k-1} E_k(\tau) + \delta_{k,2}(12/2\pi i)\tau\).

The \(a_i\) can be calculated by using \(x = \wp(\nu)\) and \(w = \wp'(\nu)\) to write

\[
\int \tilde{\lambda} = \int d\nu \ (\wp'(\nu))^2 = \frac{1}{30} \wp''' + \frac{2}{5} g_2 \zeta - \frac{3}{5} g_3 \nu
\]

(A.2)

(from standard tables or simply by differentiating the result and using (4.13)). The function \(\zeta = -\int \wp\) is not single valued and we have

\[
\zeta(\nu + \omega) - \zeta(\nu) \equiv 2\eta = \frac{\pi^2}{3\omega} E_2(\tau)
\]

\[
\zeta(\nu + \omega_D) - \zeta(\nu) \equiv 2\eta_D = \frac{\pi^2}{3\omega_D} E_2(-1/\tau) = \frac{\pi^2}{3\omega_D} E_2(\tau) - \frac{2\pi i}{\omega}
\]

(A.3)

where \(E_2(\tau) = 1 - 24q + \ldots\). This implies

\[
\eta_D \omega - \eta \omega_D = i\pi.
\]

Combining these results,

\[
a_1 \equiv \int_{\nu}^{\omega} \tilde{\lambda} = \frac{8\pi^6}{45\omega^5} (E_2(\tau) E_4(\tau) - E_6(\tau)) = -i \frac{4\pi^5}{15\omega^5} \frac{\partial}{\partial \tau} E_4(\tau)
\]

\[
a_1^D \equiv \int_{0}^{\nu} \tilde{\lambda} = \frac{8\pi^6}{45\omega_D^5} \left( E_2(-1/\tau) E_4(-1/\tau) - E_6(-1/\tau) \right) = \tau a_1 - i \frac{16\pi^5}{15\omega_D^5} E_4(\tau)
\]

(A.5)

\[
= \tau a_1 - i \frac{4\pi}{5\omega} g_2,
\]
implying \([4.13]\).
