INTRODUCTION

Fetal cystic hygromas are congenital malformations of the lymphatic system appearing as single or multiloculated fluid-filled cavities (1). About 75% of the tumors occur in the neck, with a predilection for the left side, mainly in the posterior triangle. Ten to twenty percent of the tumors occur in the axillary region and rare locations include the mediastinum, retroperitoneal area, abdominal viscera, bones, pelvis, groin, scrotum, and the chest wall (2-7). They often progress to hydrops fetalis and cause fetal death. There is a high prevalence of associated chromosomal abnormalities, Turner's syndrome being the most common.

Recently, we experienced a case of fetal axillary cystic hygroma at 38 weeks' gestation in a 30-yr-old woman. Here we report this case with a brief review of the literature.

CASE REPORT

A 30-yr-old woman with gravida 3 and para 2 was referred at 35 weeks' gestation because of a mass on the left fetal chest wall detected by routine ultrasonography performed at a private clinic at 34 weeks' gestation. There was no fetal abnormality by ultrasonography at 28 weeks' gestation at a private clinic. The patient's family history and previous medical history were unremarkable.

Her first normal child was delivered by cesarean section due to an arrest disorder 4 yr ago and second normal child was delivered vaginally 2 yr ago. In the current pregnancy, the maternal serum α-fetoprotein checked at 16 weeks' gestation was normal. Ultrasound examination, performed in our hospital at 35 weeks' gestation, revealed a 6×5 cm-sized, multiseptated cystic mass in the left axillary region of the fetus (Fig. 1). Amniotic fluid amount was normal and no other structural abnormalities were found with normal echocardiography in the fetus. Biparietal diameter, femur length, and abdominal circumference in the fetus corresponded to 35 weeks' gestation. With the diagnosis of a fetal axillary mass, elective cesarean section was performed at 38 weeks' gestation. A 3,520 g-sized male infant was delivered with Apgar scores of 10 and 10 at 1 min and 5 min, respectively. On delivery, the baby demonstrated a 6×7 cm-sized, soft cystic mass in the left axillary area (Fig. 2). No other structural anomalies were identified. Umbilical cord blood taken at the delivery revealed a normal karyotype (46, XY). Chest CT was performed on the second postnatal day (Fig. 3). It showed an 8×6 cm-sized, well-marginated cystic mass with multiple septation at the left lateral chest wall without extension to the upper neck or mediastinum.

Operation was performed on the 8th day after birth at the

Department of General Surgery and the mass was excised. Microscopically, the mass showed irregularly dilated spaces lined by flattened endothelium. There was scattering of lymphocytes in the stroma (Fig. 4). Currently, the baby grows well at the age of 1 yr and 8 months with 13.5 kg of body weight. There have been no signs of complications or sequelae.

**DISCUSSION**

The incidence of cystic hygroma is estimated to be 1:6,000 pregnancies but it is a relatively common anomaly in miscarried fetuses, with a frequency of 1:875 (8). There are many papers about cystic hygroma colli, but there are only a few
papers about fetal axillary cystic hygroma (2-4) and no domestic papers. There is no predilection for cystic hygromas by either sex (6). Cystic hygromas are generally bilateral, thin-walled, unilocular or multilocular cysts with clear to turbid fluid. In practice the term cystic hygroma is used to refer to subcutaneous cystic spaces in the neck or to loculated cystic lesions in the noncervical regions, which have a similar appearance to the nuchal cysts.

Several reviews on cystic hygroma have documented the postnatal anatomic variability (5, 10, 11). Seventy-five to ninety percent are found in the neck, 10-20% are located in the axilla (3, 7), and less than 10% are located in the extremities, trunk, abdomen, genitalia, etc.

Fetal nuchal cystic hygromas are thought to be etiologically distinct from other cystic lymphangiomas and are believed to result from inadequate drainage of the lymphatic vessels into the venous system secondary to atresia. In contradistinction, cystic lymphangioma at other locations probably develop as the lymphatic anlage grow abnormally and never achieve sufficient anastomoses with the larger lymphatic channels (12). Association with other anomalies and extension to adjacent structures leading to hydrops fetalis are frequent findings.

The frequency of a chromosomal abnormality associated with cystic hygroma may be as high as 78%. Turner syndrome being the most common (13). Prognosis for cystic hygroma is grim if the karyotype is abnormal, or if ascites and pleural fluid are present, or if bilateral pleural effusions are seen. Reichler and Bronshtein (2) reported that three of five fetal axillary cystic hygromas were associated with chromosomal abnormalities (trisomy 21 in 2 cases and trisomy 18 in 1 case). Our case showed a normal karyotype.

The survival rate progressively improves with normal karyotype, unilateral pleural effusions, atypical location and resolution of cystic hygroma (14). No single feature signifies 100% survival, however, and serial sonographic examinations are mandatory to evaluate any changes in the clinical manifestation. Once a cystic hygroma is detected, a careful search is indicated for fetal skin edema, ascites, pleural and pericardial effusions, and cardiac or renal anomalies.

Meticulous surgical excision is the treatment of choice when lesions are large. The operation is essentially conservative, since there is no justification for sacrificing any vital structures to achieve complete removal of the benign lesion (5). Most surgeons agree that the cystic hygroma should be excised when the diagnosis is made, because of the risk of severe complications. This advice should be modified if an important structure is involved and the surgery can be delayed for 6 months or 1 yr until the child has had an opportunity to grow (15). Other types of treatment have been proposed as adjuvants such as radiotherapy, injection of sclerosing agents, aspiration, and carbon dioxide laser, which are controversial (5, 15, 16). Conservative management with observation has been recommended by some surgeons in asymptomatic patients (16).

Because only small numbers of fetal cystic hygroma have been reported so far, it is uncertain if axillary cystic hygromas carry a marked risk for aneuploidy or untoward pregnancy outcome.
