Abstract

There are very few cases of clear cell renal cell carcinoma with metastases to the vagina and brain reported in the literature. Our case study highlights this rare clinical occurrence and its associated complications including pulmonary embolism. In addition we discuss current management guidelines for treating and diagnosing the disease, and how this management improves prognosis.

Case Report

Presentation and history

A 55-year-old African American female with a past medical history of hypertension, nicotine dependence (stopped smoking eleven years ago), and Para 2022 (status post-right salpingectomy for ectopic pregnancy) presented with six weeks of persistent postmenopausal bleeding per vagina (PV). Prior to presentation the patient had been menopausal for ten years and used only amlodipine and valsartan tablets as medications. She has a positive family history (sister) of breast cancer and denied intra-uterine exposure to diethyl stilbestrol (DES). The physical examination revealed a loose necrotic mass with a pedunculated polyp attached to the posterior wall of the vagina and measuring 3.5x1.5x1 cm. Endocervical and endometrial curetting were negative for malignancy while polypectomy of the vaginal mass revealed foci of necrosis, surface ulceration, and a polyoid tumor consistent with clear cell carcinoma of the vagina (Figure 1).

Initial management

A computerized tomography (CT) scan of the abdomen with contrast had been done four months previously and showed a 4.4 cm left kidney mass with peripheral enhancement. A CT scan of the chest, abdomen, and pelvis done after the diagnosis of clear cell malignancy revealed a pulmonary embolism (PE) in the left lower lobe pulmonary arteries, an enlarged area of enhancement measuring 7 cm in the inferior aspect of the left kidney (Figure 2), and a 6x5.6 cm focus of soft tissue enhancement in the region of the vagina (Figure 3). These findings were suggestive of cystic renal cell carcinoma and metastatic clear cell carcinoma of the vagina, respectively.

Treatment

The patient was started on Lovenox (enoxaparin) and coumadin, but she started bleeding PV a week later and was admitted to our inpatient service with shortness of breath, and for anticoagulation treatment and inferior vena cava filter placement. She later underwent a laparoscopic hand-assisted left nephrectomy with histopathological examination of the 6.6x6x4.5 cm left lower kidney pole specimen, which was consistent with renal clear cell carcinoma (Figure 4). The tumor extended into the left perirenal adipose tissue, was a Fuhrman nuclear grade G3 tumor, involved the left renal vein, and was staged as T3bN0Mx secondary to the vaginal metastases.

Clinical course and outcome

The patient tolerated surgery well, and after discharge received palliative radiation therapy (4860 cGy in 27 fractions of 180 cGy) to the pelvis. However, she was re-admitted three months after discharge for persistent headaches and right-sided upper extremity numbness and weakness, which on CT of the head was found to be because of a secondary left posterior parietal mass. She underwent an intracranial incision biopsy of the left parietal brain tumor that showed metastatic clear cell carcinoma histologically, consistent with a renal primary tumor. She received postoperative therapeutic irradiation of the cranium for metastatic brain lesions and recently was started on chemotherapy (Sutent 50 mg once daily orally). She continues taking her antihypertensive medication but had to discontinue her anticoagulation drugs because of recurrent PV bleeding. She currently has good performance status and otherwise is stable medically.

Discussion

Epidemiology

Clear cell renal cell carcinoma (RCC) is the most common primary site for clear cell tumors, yet clear cell RCC metastases to the vagina or brain are rare with only one case of the former reported in the literature to date.8 Eighty cases of RCC with vaginal metastases have been reported in the literature,8 and because clear cell carcinomas constitute about 80% of all renal cell carcinomas,8 most of these cases may be clear cell carcinomas in fact, but are under-reported as such. Clear cell RCC usually occurs in the sixth or seventh decade of life and is three times more common in men than in women.2

Clinical presentation

The most common symptom on presentation in RCC cases with vaginal metastases is vaginal bleeding,7 and its most common sites for metastases include extra-renal regions like lung, lymph nodes, liver, and bones.1 Our case was unique for its metastatic sites, clinical presentation, and associated complications. Clear cell RCC with metastases to the vagina and brain is very uncommon with one case of the former1 and none of the latter reported in the literature. In postmenopausal women only one case of primary clear cell carcinoma of the vagina has been reported9 because these tumors tend to occur more in young patients exposed to DES in utero.4 Therefore, a solitary lesion of clear cell carcinoma in the vagina in a postmenopausal patient is more likely to be a metastatic secondary than a primary lesion, and a consideration of clear cell tumor primary sites should be performed immediately. This was done in our case and revealed a primary site in the left kidney, which is typically the primary site for clear cell RCC as the retrograde filling of the left renal vein from the left ovarian vein and uretovaginal plexus eventually involves the left kidney.3

Complications

The vascular effects of clear cell RCC involve the intravascular growth of the tumor into the left renal vein, and may have caused the tumor emboli to the left lower lung pulmonary arteries that resulted in our patient’s pulmonary embolism. The vascular involvements of clear cell carcinoma are well documented in the literature but this is the first reported case with an associated pulmonary embolism.

Diagnostic methods

Fine needle aspiration cytology to establish the anatomic site of origin in metastatic clear cell RCC cases, when combined with clinical features, is 95% accurate and is easier to administer in outpatient settings and follow-up cases than are endometrial biopsies. However, the use of magnetic resonance imaging (MRI) and CT scans still provide the mainstay of primary clear cell RCC diagnoses (and subsequent diagnoses of secondary metastases) owing to their greater utility and accuracy.

Treatment

The use of whole body radiation therapy in cases involving a solitary metastatic site clear cell carcinoma currently is not recommended as adjuvant loco-regional radiation therapy is the preferred treatment for clear cell RCC. In diffuse or non-resectable disease, or when paraneoplastic syndrome, severe hemorrhage, or severe pain is present, however, the use of palliative nephrectomy is recommended.

Prognosis

Multiple metastases, recurrent metastases, and renal vein involvements are poor prognostic indicators for survival and, as seen in our patient, are prone to develop complications like pulmonary embolism. Patients with multifocal clear cell RCC (like our patient with two metastatic sites) are more likely to have a contralateral recurrence than are patients with solitary clear cell RCC (risk ratio: 2.91, p=0.142).

Conclusions

The development of recurrent shortness of breadth in a clear cell RCC patient with vaginal metastases is indicative of pulmonary embolism, and the presence of neurological deficits is suggestive of brain metastases. A high indicative index for a clear cell primary tumor is a requirement for the diagnosis of a secondary clear cell vaginal malignancy and for avoiding complications like pulmonary embolism, further metastatic spread, and the consequent deterioration of the patient.
