Abstract
The ASACUSA collaboration at the Antiproton Decelerator of CERN aims at a precise measurement of the antihydrogen ground-state hyperfine structure as a test of the fundamental CPT symmetry. A beam of antihydrogen atoms is formed in a CUSP trap, undergoes Rabi-type spectroscopy and is detected downstream in a dedicated antihydrogen detector. In parallel measurements using a polarized hydrogen beam are being performed to commission the spectroscopy apparatus and to perform measurements of parameters of the Standard Model Extension (SME). The current status of antihydrogen spectroscopy is reviewed and progress of ASACUSA is presented.

Keywords Antihydrogen · CPT · Hyperfine spectroscopy · Matter-antimatter symmetry
1 Antihydrogen and CPT symmetry

CPT symmetry is a cornerstone of the Standard Model (SM) of particle physics due to the existence of the CPT theorem which states that any Lorentz-invariant, unitary, local field theory of point-like particles is invariant under the combined operation of charge conjugation C, parity P and time reversal T. The observed matter - antimatter asymmetry in the Universe as well as theories beyond the SM like string theory, where some of the prerequisites of the mathematical proof of the CPT theorem do not hold any more, have encouraged experimental tests of CPT symmetry.

One of the consequences of the CPT theorem is that particles and antiparticles have exactly the same (mass, total lifetime) or exactly the opposite (charge, magnetic moment) properties. An overview of existing measurements is available at the Particle Data Group [1], some of the standard measurements of masses of elementary particles and antiparticles are shown in Fig. 1 (a more elaborate comparison including e.g. \( g \)-factor measurements as performed by the BASE collaboration to ppb precision [6] is possible within the Standard Model Extension (SME) framework [7–9]).

From Fig. 1 it becomes evident that atomic physics measurements like the cyclotron frequency of protons and antiprotons in a trap yielding the charge-to-mass ratio \( q/m \) and determinations of the internal structure of antihydrogen offer the most sensitive tests of CPT symmetry on an absolute scale. The potential of antihydrogen, the simplest anti-atom whose matter equivalent hydrogen is one of the best studied systems in physics, for precision CPT tests has been realized early [10], the most difficult challenge being the formation of cold antihydrogen atoms suitable for spectroscopy. At the Antiproton Decelerator of CERN now

In case of Lamb shift: orange: estimated achievable accuracy, paler orange: accuracy for hydrogen. Values are from PDG [1] except for H results for HFS [2], 1 S–2 S [3], and Lamb shift [4]. p charge-to-mass ratio [5], note that in this case only the position is of the left hand side is well defined, while the right hand side is less precise since the cyclotron frequency is proportional to the magnetic field in which the measurement is taken.](image-url)
several experiments are routinely producing antihydrogen [11], with the ALPHA collaboration having been able to perform first spectroscopy measurements recently [2, 3, 12].

ASACUSA is aiming at a measurement of the antihydrogen ground-state hyperfine structure GS-HFS [13, 14], transporting the $\overline{\text{H}}$ atoms to a region far away from the stray magnetic fields at the formation region, like it was done for hydrogen by Rabi [15] and others. This will ultimately allow for precision exceeding the one of in-trap hyperfine spectroscopy as done in [3].

2 Antihydrogen beam formation and hyperfine spectroscopy

In ASACUSA antihydrogen atoms are formed from their ingredients [16]. Antiprotons from the CERN Antiproton Decelerator are trapped and cooled in a Penning trap MUSASHI [17]. Positrons are produced by a $^{22}\text{Na}$ source in combination with a solid Ne ice moderator, they are accumulated in a Surko type buffer gas trap. Both species are brought together and mixed in a magnetic CUSP configuration [18] using a nested Penning trap configuration [19] which is widely used at the AD.

Figure 2 (left) shows a schematic view of the Rabi-type beam spectroscopy experiment. Figure 2 (right) depicts the behavior of the four hyperfine states characterized by the quantum number $F$ connected to the total spin $\mathbf{F} = \mathbf{S}_1 + \mathbf{S}_2$ and its projection $M$ to the quantization axis. States with increasing (decreasing) energy in an external magnetic field are called low-field seekers (high-field seekers). Two possible transitions induced by microwaves ($\sigma_1, \pi_1$) that are accessible in this experiment are denoted by arrows.

After the initial success of $\overline{\text{H}}$ formation [20], a beam of cold antihydrogen atoms was observed 2.7 m downstream of the formation region [21]. In 2017 for the first time the principal quantum number distribution could be measured using the antihydrogen detector [22] and a field ionization stage, which – as expected from three-body formation – contains mainly Rydberg atoms [23]. $\overline{\text{H}}$ with $n < 14$ were detected with 4.5 $\sigma$ significance, which could within their life time of $\sim 100 \mu\text{s}$ decay to the ground state before reaching the cavity. The overall observed rate of such events of $\sim 0.001 \text{s}^{-1}$ is however far too small for
spectroscopy measurements. The primary task is to increase the production rate of ground-state antihydrogen by 1–2 orders of magnitude.

3 Hydrogen hyperfine spectroscopy results

Due to the scarce availability of antihydrogen, ASACUSA decided to develop a hydrogen beam with the initial goal to commission the hyperfine spectroscopy apparatus. A source of cold polarized hydrogen with a temperature of \( \sim 50 \) K as expected for the \( \bar{H} \) formed in the CUSP was connected to the microwave cavity and superconducting sextupole magnet to be used for antihydrogen spectroscopy. For hydrogen detection a commercial Q-mass spectrometer was used. With this setup the \( \sigma_1 \) transition in hydrogen could be determined to a few Hertz precision at \( \nu \sim 1.42 \) GHz, resulting in a 2.7 ppb measurement of the hydrogen GS-HFS [24]. This constitutes the most precise determination of this quantity in a beam so far, the highest precision of 2 mHz having been obtained in a hydrogen maser [25, 26], which cannot be used for antimatter. The result using the \( \sigma_1 \) transition also allows us to estimate that with this method about 8000 \( \bar{H} \) atoms in the ground state are needed to obtain a precision of \( \sim 1 \) ppm, which is the initial goal of ASACUSA.

While many coefficients of the minimal SME have been constrained by hydrogen maser measurements, in the newly developed non-minimal SME a set of coefficients is present that has not yet been investigated experimentally [27], especially those depending on the orientation of the static magnetic field with respect to the Earth rotation axis [23]. Within the SME, the \( \pi_1 \) transition is sensitive to CPT violations while the \( \sigma_1 \) transition is not. Since the \( \pi_1 \) transition is more sensitive to magnetic field inhomogeneities, we constructed new McKeehan-like coils [28] and a three-layer cylindrical shielding [29]. Additionally we changed the beam optics so to produce the same rate of hydrogen atoms in the different quantum states at the detector [30], using permanent sextupole magnets and ring apertures. With this setup, first measurements were done determining alternatingly the transition frequencies \( \nu_{\pi} \) and \( \nu_{\sigma} \) at each setting of the external constant magnetic field \( B_{\text{ext}} \), which is controlled by the McKeehan-like coils. Figure 3 shows preliminary measurements of \( \nu_{\sigma} \) and \( \nu_{\pi} \) at several \( B_{\text{ext}} \). The \( B \)-field dependence of the two transitions follows from the Breit-Rabi formula [31], yielding a hyperbolic dependence of \( \nu_{\sigma} (B_{\text{ext}}) \) and a dominantly linear
Table 1 Hydrogen ground-state hyperfine splitting results using the ASACUSA hydrogen beam (preliminary)

|                  | ν₀ [Hz] | Relative error | ν₀ − ν₈t [Hz] |
|------------------|---------|----------------|--------------|
| σ₁ extrapolation | 1 420 405 767(15) | 1.04 × 10⁻⁸ | 15 |
| π₁ extrapolation | 1 420 405 760(34)  | 2.38 × 10⁻⁸ | 8  |
| Mean value of the two extrapolations | 1 420 405 766(14)  | 9.96 × 10⁻⁹ | 14 |
| ν₀ and ν₈determined at same static magnetic field | 1 420 405 753(8)  | 5.60 × 10⁻⁹ | 1  |

The results agree within 1 standard deviation to the literature value ν₈t obtained by a hydrogen maser [25]. From [29]

one for ν₈(B₈ext). Table 1 gives the values of the hyperfine transition frequency ν₀ obtained by extrapolating each type of transition to zero external field, yielding typical precisions of a 10–30 ppb in a first test run lasting five days.

Instead of extrapolations, the measurement of ν₀ and ν₈ at the same B₈ext can be used to directly determine the zero-field GS-HFS frequency ν₀ [32]. This method, using the same data sets, leads to a factor 2 smaller errors than the individual extrapolations and is of interest to antihydrogen, as it includes the more interesting π₁ transition and requires the acquisition of only two resonances to predict the zero-field value (thereby reducing the amount of required H events to 4000 for a ~ 1 ppm result). Further tests of this method are ongoing and systematic measurements of both ν₀ and ν₈ are planned in the near future.

4 Summary and outlook

The ground-state hyperfine splitting of antihydrogen offers one of the most sensitive tests of CPT symmetry. ASACUSA is preparing an antihydrogen beam for an in-flight measurement of this quantity using a Rabi-type spectroscopy method which has the advantage of being performed in a field-free environment. The rate of antihydrogen formation in the CUSP needs further improvement of 1–2 orders of magnitude to allow for spectroscopy measurements.

In parallel in-beam hyperfine spectroscopy of ordinary hydrogen is pursued. A first measurement using the same cavity and sextupole as will be employed for antihydrogen resulted in a 2.7 ppb precision showing that the spectroscopy method is fully functional. Using the hydrogen beam, measurements are under way to determine coefficients of the non-minimal Standard Model Extension that have so far not been experimentally constrained.
