Understanding how hematopoietic stem cells (HSCs) are generated and the signals that control this process is a crucial issue for regenerative medicine applications that require in vitro production of HSC. HSCs emerge during embryonic life from an endothelial-like cell population that resides in the aorta–gonad–mesonephros (AGM) region. We show here that β-catenin is nuclear and active in few endothelial nonhematopoietic cells closely associated with the emerging hematopoietic clusters of the embryonic aorta during mouse development. Importantly, Wnt/β-catenin activity is transiently required in the AGM to generate long-term HSCs and to produce hematopoietic cells in vitro from AGM endothelial precursors. Genetic deletion of β-catenin from the embryonic endothelium stage (using VE-cadherin–Cre recombinase), but not from embryonic hematopoietic cells (using Vav1–Cre), precludes progression of mutant cells toward the hematopoietic lineage; however, these mutant cells still contribute to the adult endothelium. Together, those findings indicate that Wnt/β-catenin activity is needed for the emergence but not the maintenance of HSCs in mouse embryos.
increase Ca$^+$ or Rho/Rac GTPases to activate JNK (Malhotra and Kincade, 2009). The canonical pathway is characterized by the inhibition of glycogen synthase kinase 3β (GSK3-β)–dependent phosphorylation of β-catenin, thus blocking its degradation and resulting in its nuclear translocation and activation of β-catenin/TCF-responsive genes. Inhibition of GSK3-β activity is mediated by dishevelled and involves the disruption of a catalytic complex (also known as the destruction complex) formed by Axin, adenomatous polyposis coli (APC), casein kinase I, and GSK3-β. Whether Wnt/β-catenin is required for maintaining adult HSCs is controversial; whereas conditional deletion of β-catenin (using Vav1-cre), its inhibition by Dickkopf 1 (DKK1), or Wnt3a deficiency in HSC impairs self-renewal (Reya et al., 2003; Fleming et al., 2008; Luis et al., 2009), inducible deletion of β/γ-catenin genes in BM does not have such effect (Jeannet et al., 2008; Koch et al., 2008). In contrast, ectopic activation of Wnt/β-catenin in vitro enhanced HSC activity, and it was initially interpreted as an effect on HSC expansion (Reya et al., 2003; Goessling et al., 2009). More recently, it has been shown that gain-of-function mutations of β-catenin in vivo result in the exhaustion of this compartment (Kirstetter et al., 2006; Scheller et al., 2006; Renström et al., 2009; Lane et al., 2010). Altogether, this suggests that a delicate balance of the Wnt/β-catenin activity is required to maintain HSC integrity (Malhotra and Kincade, 2009).

Although Wnt has been shown to be important for HSC specification in the zebrafish AGM (Goessling et al., 2009), nothing is known about its role in the generation, amplification, or maintenance of HSCs in the mammalian embryo. To investigate this possibility, we have now extensively characterized different subpopulations of the aorta/AGM endothelium for the activation status of Wnt/β-catenin. We also studied the effect of β-catenin intervention to generate HSCs and show that Wnt/β-catenin activity is transiently required in the AGM to generate long-term HSCs. Finally, we demonstrate that β-catenin is required in the embryonic VEC-expressing cells to contribute to the adult hematopoiesis.

RESULTS

Wnt/β-catenin activity is restricted to few endothelial nonhematopoietic cells in the AGM

The AGM region contains different subtypes of endothelial and hematopoietic precursors at different stages of differentiation toward definitive cells of these lineages. Cells with hematopoietic traits that emerge in clusters from the aorta endothelium can be distinguished from the rest of endothelial cells by the expression of the c-kit receptor (CD117; Yokomizo and Dzierzak, 2010), whereas cells already determined to the hematopoietic lineage, including HSCs, are identified by the expression of CD45. To investigate the mechanisms regulating the endothelial to hematopoietic transition, we compared the expression profile of two endothelial-like cell populations of the AGM based on c-kit expression: 31K$^-$ (CD31$^+$ c-kit$^+$ CD45$^-$) and 31K$^+$ (CD31$^+$c-kit$^+$CD45$^+$; Fig. 1 A). We found that several Wnt family genes were highly enriched in the 31K$^-$ population compared with 31K$^+$ (Fig. 1 B and C). Moreover, several Wnt genes, including Wnt3a, are expressed in the endothelium and hematopoietic clusters of E10.5 AGM (unpublished data). Thus, we investigated the activation status of the Wnt/β-catenin pathway in nonmanipulated AGMs using the 8E7 antibody, which detects the nonphosphorylated form of β-catenin (directed to Ser37 and Thr41) and recognizes nuclear active β-catenin (ABC; Staal et al., 2002). By immunostaining with this antibody, we found a large accumulation of nonphosphorylated β-catenin in the cytoplasm of most endothelial cells (Fig. 1 D) and in the nucleus of a few cells at the base of the presumptive hematopoietic clusters (Fig. 1 D, detail). By double immunostaining with anti-c-kit antibody, we observed that cells containing nuclear β-catenin were c-kit$^-$ but were closely associated with the c-kit$^+$ cells (Fig. 1 E). In addition, these cells express the marker CD31 (Fig. 1 F) and are positive for anti-β-galactosidase staining in the TOPGAL reporter embryos, which is commonly used as readout for Wnt/β-catenin activation (DasGupta and Fuchs, 1999; Fig. 1 G). Then, we sorted 31K$^-$ and 31K$^+$ cells on slides and performed immunofluorescence with the ABC antibody. We detected nuclear β-catenin in 5.92 ± 1.77% of the 31K$^-$ fraction (endothelial), whereas the 31K$^+$ (pream- 

β-Catenin activity is required at embryonic day 10.5 (E10.5) to generate HSCs in the AGM

To functionally evaluate whether β-catenin activity regulates HSC generation in the AGM, we tested the effect of pharmacological inhibitors or activators of the pathway on explant cultures (Fig. 2 A, scheme). This culture system has been extensively used to maintain and amplify the embryonic HSC pool (Medvinsky and Dzierzak, 1996). As a β-catenin activator, we used the GSK3-β inhibitor SB216763 which stabilizes β-catenin at the protein level (Driessens et al., 2010), and as inhibitor we used PKF-115-584 which blocks the interaction between β-catenin and TCF (Lepourcelet et al., 2004). As control, we confirmed that SB216763-treated explants showed increased levels of total and nuclear β-catenin (not depicted) and higher expression of the β-catenin target genes Axin2 and Lef1 (Fig. 2 B), whereas PKF-115 treatment reduced EphB2 and CyclinD1 transcription (Fig. 2 B). We found that β-catenin activation by SB216763 increased the number of colony-forming cells (CFCs) in the explants, which was statistically significant when considering BFU-E (burst-forming unit erythroid) and CFC-Mix colonies. In contrast, β-catenin inhibition led to a reduction of all CFC types, although only CFC-GM (granulocyte–macrophage CFC) reduction reached statistical significance (Fig. 2 C). We next determined the capacity of these AGM explants to generate colonies in the spleen 11 d after transplantation (CFU-S$^{+}$) as a measure of the most undifferentiated myeloid progenitors. We found that treating E10.5 AGMs with SB216763 resulted
Finally, we investigated the possible effect of β-catenin modulation in the generation of HSCs by hematopoietic reconstitution of lethally irradiated mice, using single AGM explants untreated or treated with the different compounds. Our results showed that E10.5 AGM cells showed a poor long-term repopulation capacity in the control (one out of six) and PKF-115–treated (zero out of seven) explants (Fig. 2 F, left). However, when animals were transplanted with 2 embryo equivalents (2 ee; 2 AGM explants), in a twofold increase in the number of CFU-S11, whereas PKF-115 reduced the number of these colonies by threefold (Fig. 2 D). Interestingly, inhibiting β-catenin at E11.5 no longer had any effect in the number of CFU-S11 progenitors (Fig. 2 E), indicating a stage-dependent requirement for β-catenin activity.
we detected hematopoietic reconstitution from the control-treated donor cells in three out of four recipients and HSC activity was essentially lost after PKF-115 treatment (Fig. 1 G). Importantly, single SB216763-treated explants (1 ee) displayed robust engraftment capacity (7 out of 11 animals, P = 0.0029 compared with DMSO control) with a mean contribution of >70% of donor cells in the recipient animal (Fig. 2 F, left). Consistent with the results obtained in the CFU-S₁₁ assays, parallel transplantation experiments using E11.5 AGM explants (1 ee) showed no differences in the repopulation capacity of treated explants compared with the controls (Fig. 2 F, right). However, a more accurate quantification of the HSC activity by limiting dilution experiments demonstrated that E11.5 AGMs were still responding to β-catenin modulation because SB216763 treatment significantly increased the reconstitution capacity of the AGM explants when 0.25 ee was transplanted (Fig. 2, H and I). Most importantly, SB216763-treated HSCs preserved their self-renewal capacity as was detected hematopoietic reconstitution from the control-treated donor cells in three out of four recipients and HSC activity was essentially lost after PKF-115 treatment (Fig. 1 G). Importantly, single SB216763-treated explants (1 ee) displayed robust engraftment capacity (7 out of 11 animals, P = 0.0029 compared with DMSO control) with a mean contribution of >70% of donor cells in the recipient animal (Fig. 2 F, left). Consistent with the results obtained in the CFU-S₁₁ assays, parallel transplantation experiments using E11.5 AGM explants (1 ee) showed no differences in the repopulation capacity of treated explants compared with the controls (Fig. 2 F, right). However, a more accurate quantification of the HSC activity by limiting dilution experiments (1, 0.5, and 0.25 ee) demonstrated that E11.5 AGMs were still responding to β-catenin modulation because SB216763 treatment significantly increased the reconstitution capacity of the AGM explants when 0.25 ee was transplanted (Fig. 2, H and I). Most importantly, SB216763-treated HSCs preserved their self-renewal capacity as...
demonstrated by secondary transplants from animals engrafted with E10.5-- (not depicted) and E11.5 (Fig. 2 J)--treated AGM explants. On the contrary, AGM and fetal liver (FL) cells from embryos carrying an APC mutation (APC<sup>Min/+</sup>; Groden et al., 1991) that show constitutive β-catenin activation displayed a markedly decrease in the HSC self-renewal capacity in secondary transplants (unpublished data), similar to that reported for APC<sup>Min/+</sup> BM cells (Lane et al., 2010; Wang et al., 2010).

Together, these results indicate that HSC generation in the AGM is totally dependent on β-catenin at E10.5, whereas already formed HSCs contained in the E11.5 AGM are β-catenin independent. However, the HSC pool can still be increased by activating β-catenin at this later stage.

### β-Catenin favors hematopoietic differentiation from endothelial precursors

We next investigated the mechanisms underlying the requirement of β-catenin on the generation of HSCs in the AGM. By flow cytometry analysis, we did not detect any change in proliferation or apoptosis (measured by Annexin V binding) in the CD31<sup>+</sup> population from different AGM-treated explants (Fig. 3, A and B). Ki67 (proliferation) and TUNEL (apoptosis) staining of sorted 31K<sup>+</sup> and 31K<sup>−</sup> cells confirmed these results (Fig. 3 C, table).

We then analyzed whether Wnt/β-catenin modulators affected the relative percentage of endothelial (CD31<sup>+</sup>c-kit<sup>−</sup>) and hematopoietic precursor (CD31<sup>+</sup>c-kit<sup>+</sup>) cells in the AGM explants. Our results demonstrated that Wnt/β-catenin inactivation significantly decreased the percentage of hematopoietic cells while increasing the endothelial lineage (Fig. 3 D). Conversely, SB216763 treatment resulted in a slight increase in the percentage of hematopoietic precursors (Fig. 3 D), which mimics the effect of the APC mutation in AGM explants (not depicted). These results indicate that β-catenin activity is required to support hematopoietic commitment of the AGM precursors without affecting proliferation or apoptosis of the CD31<sup>+</sup> population.

### 31K<sup>−</sup> cells produce hematopoietic cells dependent on β-catenin activation

As we found that the 31K<sup>−</sup> fraction included the cells containing nuclear β-catenin, we directly tested the effects of Wnt modulators on this population compared with the 31K<sup>+</sup>. With this aim, we performed in vitro cultures of sorted populations using SB216763 or Wnt3a as activators of β-catenin and PKF-115 or DKK1 as β-catenin inhibitors (Fig. 4, A and B; and Fig. S1).

We found that untreated or treated 31K<sup>−</sup> cells from either E10.5 (Fig. 4 H, left) and E11.5 (Fig. 4 D) produced comparable numbers and percentages of hematopoietic cells as measured by flow cytometry analysis (example in Fig. 4 C) and CFC hematopoietic colony assays (not depicted). Similarly, control or β-catenin--activated (SB216763 and Wnt3a) 31K<sup>−</sup> cultures from E11.5 AGM produced both adherent and nonadherent round-shaped cells after 8 d of culture (Fig. 4 F) that mostly expressed the CD45 hematopoietic marker (Fig. 4 E), whereas β-catenin activation significantly potentiated the hematopoietic capacity of E10.5 cultures (Fig. 4 H, right). Conversely, inhibition of β-catenin by the pharmacological inhibitor PKF-115 almost abolished the generation of hematopoietic cells from 31K<sup>−</sup> precursors (Fig. 4, E and F) and the capacity of these cells to form hematopoietic colonies in CFC assays from E11.5 AGMs (Fig. 4 G).

Similarly, the use of the recombinant DKK1 inhibitor
whether deletion of β-catenin in the embryonic endothelium prevented the generation of hematopoietic cells in vivo. We tested this by using a mouse model expressing Cre recombinase under the control of the VEC promoter (VEC-Cre; Zovein et al., 2008) crossed with the R26R fl-stop-fl-YFP mouse to trace Cre activity. Flow cytometry analysis confirmed that VEC-derived YFP-expressing cells are present in the E11.5 AGM (2 ± 0.7% of CD31+ cells) and contribute to the hematopoiesis of E12.5 FL (15.45 ± 2.25% of CD45+ cells; not depicted) and all adult hematopoietic lineages (20.5 ± 3.5% BM; 16.8 ± 1.8 spleen; 20.4 ± 3.4 thymus; see Fig. 6 D and Fig. S2 C).

As an additional control, we found that sorted CD31− population (after exclusion of CD45+ c-kit+ cells) cultured in the same conditions failed to generate CD45+ hematopoietic cells, even when 30-fold more cells were seeded (unpublished data). Together these results indicate that the 31K− cells contain the hemogenic precursors that depend on Wnt/β-catenin activation to generate hematopoietic cells.

β-Catenin activity in the embryonic endothelium is required to produce adult hematopoietic cells in vivo

Because Wnt/β-catenin–responding cells are contained within the endothelial 31K− population, we further investigated whether deletion of β-catenin in the embryonic endothelium prevented the generation of hematopoietic cells in vivo. We tested this by using a mouse model expressing Cre recombinase under the control of the VEC promoter (VEC-Cre; Zovein et al., 2008) crossed with the R26R fl-stop-fl-YFP mouse to trace Cre activity. Flow cytometry analysis confirmed that VEC-derived YFP-expressing cells are present in the E11.5 AGM (2 ± 0.7% of CD31+ cells) and contribute to the hematopoiesis of E12.5 FL (15.45 ± 2.25% of CD45+ cells; not depicted) and all adult hematopoietic lineages (20.5 ± 3.5% BM; 16.8 ± 1.8 spleen; 20.4 ± 3.4 thymus; see Fig. 6 D and Fig. S2 C). Next, we crossed these mice with the β-catenin floxed line (flanking Exon3 to Exon6; Fig. 5 A) and analyzed the contribution of YFP+ cells to the embryonic and adult hematopoiesis. We detected YFP expression in the endothelium of both heterozygous and homozygous mutant embryos (Fig. 5 B). Determination of functional hematopoietic progenitors by CFC assays in the AGM from the different genotypes demonstrated a strong and significant reduction in these cultures resulted in a decrease in the production of hematopoietic cells, reaching statistical significance when comparing total CD45+ cells (P = 0.043). In contrast, the 31K− population from E10.5 AGM produced very few hematopoietic cells in basal conditions (without exogenous β-catenin activation); thus, the inhibition of the pathway by PKF-115 did not have any effect as expected (Fig. 4 H).

As an additional control, we found that sorted CD31− population (after exclusion of CD45+ c-kit+ cells) cultured in the same conditions failed to generate CD45+ hematopoietic cells, even when 30-fold more cells were seeded (unpublished data). Together these results indicate that the 31K− cells contain the hemogenic precursors that depend on Wnt/β-catenin activation to generate hematopoietic cells.
the number of progenitors in the β-catenin fl/fl VEC-CRE+ E10.5 and E11.5 AGMs (Fig. 5 C), but not in E11.5 FL (not depicted), compared with the wild-type or heterozygous littermates. Analysis of individual colonies by PCR (Fig. 5 D) showed that the few colonies obtained from the β-catenin fl/fl VEC-CRE+ AGM were generated from cells that failed to efficiently delete the floxed alleles (only 10% of colonies showed a total deletion), suggesting a strong requirement for β-catenin in the developing hematopoietic lineage. In agreement with this, analysis of E14.5 FL showed the presence of some mutant lineage sca1+c-kit+ (LSK+) YFP+ cells (Fig. 5 E) that displayed increased apoptosis as determined by AnnexinV binding (Fig. 5 F). Moreover, analysis of E17.5–18.5 fetuses revealed that most β-catenin fl/fl VEC-CRE+ mutants (seven out of eight) were pale and showed obvious hemorrhages, indicative of both vascular and hematopoietic defects (Fig. 6 B). Importantly, β-catenin-deficient fetuses (E17.5–18.5) have a fivefold reduction in the total FL cellularity, with a threefold reduction in the LSK population and the complete absence of YFP+ cells, as determined by flow cytometry (Fig. 6 C). Accordingly, deletion of both β-catenin alleles resulted in perinatal lethality, and only 12% of mutant

Figure 5. β-catenin deletion has a deleterious effect on the embryonic hematopoietic progenitors. (A) Conditional deletion of β-catenin in the endothelium. animals were found at weaning (Fig. 6 A and Fig. S2 A). Moreover, these mutant animals showed no contribution of β-catenin-deleted (YFP⁺) cells to the adult hematopoiesis (Fig. 6 D and Fig. S2 B), whereas deletion of one β-catenin allele (β-cat fl/fl) reduced the percentage of YFP⁺ cells in the BM and spleen without affecting viability. Similarly, we did not detect any β-catenin–deleted hematopoietic cells in irradiated mice reconstituted with E14.5 FL β-catenin fl/fl VEC-CRE⁺ cells (unpublished data), which precluded further analysis of β-catenin deletion in HSC. However, YFP⁺ cells of all genotypes similarly contributed to the adult endothelium of the liver (Fig. 6 F) and kidney (not depicted), suggesting that β-catenin was specifically required for HSC generation after endothelial determination. To study whether β-catenin deletion had any effect in already generated embryonic HSCs, we next induced β-catenin deletion by Vav1-CRE (combined with the YFP floxed allele), which targets hematopoietic cells after the acquisition of CD45 and VEC loss (Chen et al., 2009). We found that deletion of either one or two β-catenin alleles in this mouse model did not

(G) Model of Wnt/β-catenin activity in the embryonic AGM. Wnt/β-catenin signaling is required in the endothelial-like cells to generate hematopoietic progenitors and stem cells but gradually decreases after hematopoietic commitment.
affect the contribution of YFP+ cells to the adult hematopoiesis (Fig. 6 E; and Fig. S2, D and E), similar to previously published data (Zhao et al., 2007). Together, our genetic data and the results obtained with pharmacologic modulators of Wnt indicate that β-catenin activity is required in the VEC-expressing cells before the stage of Var1 expression (around E10–11) to generate HSCs and their progeny in a dose-dependent fashion (Fig. 6 G, model).

**DISCUSSION**

To better understand the development of HSCs, we have investigated the role of Wnt/β-catenin signaling in the mouse embryonic aorta in the AGM region at midgestation. The AGM region exhibits activated β-catenin (as well as β-catenin activity) in a small subpopulation of endothelial-like cells. We have demonstrated that embryonic endothelial cells lacking β-catenin activity (by pharmacological inhibition or genetic deletion) preclude their contribution to generate HSCs and contribute to the hematopoiesis of the adult organism.

Wnt canonical pathway is important in the maintenance of several types of stem cells such as intestinal, epidermal, or mammary (Reya and Clevers, 2005); however, some questions still remain about the role of β-catenin for the generation and maintenance of HSCs. It has been shown that activation of β-catenin in BM hematopoietic precursors increases the pool of cells with long-term repopulating capacity (Reya et al., 2003; Willert et al., 2003; Goessling et al., 2009) or induces B cells to express HSC markers (Malhotra et al., 2008). Nevertheless, work from different groups has demonstrated that forced β-catenin activity results in the exhaustion of the stem cell compartment by affecting its self-renewal capacity (Kirstetter et al., 2006; Scheller et al., 2006). In addition, impaired β-catenin activation in HSCs (by DKK1 expression [Fleming et al., 2008] or deletion of β-catenin [Zhao et al., 2007] or Wnt3a [Luis et al., 2009]) also has a negative effect on self-renewal. Together these results support a requirement of the just-right dose of β-catenin activity in the HSC compartment (Malhotra and Kincade, 2009; Luis et al., 2011). Instead, our results show that the activity of β-catenin in the embryonic aorta is required in a dose-dependent manner during the generation of HSCs (around E10.5) but not thereafter. Our results are in agreement with previous observations in zebrafish, showing a positive effect of β-catenin activation on HSC formation in the zebrafish AGM through a PKA-dependent mechanism downstream of prostaglandin E2 (Goessling et al., 2009). Although we have not addressed the participation of prostaglandin E2/protein kinase A or other pathways for the activation of β-catenin and requirement for HSC commitment, these observations support the idea that the process is evolutionarily conserved. Deletion of β-catenin by VEC-Cre led to high mortality around birth that is partially a result of the hematopoietic defects but also of the endothelial defects as indicated by the presence of hemorrhages. This phenotype is compatible with that observed for specific endothelial Tie2-Cre–driven β-catenin deletion, although these mutants showed 100% lethality at early E13.5 (Cattelino et al., 2003), which may reflect a higher level of Cre expression.

It was demonstrated that HSCs originate from endothelial precursors expressing VEC during embryonic development (Zovein et al., 2008; Chen et al., 2009). However, many questions concerning the biology of this process remain unanswered, such as whether embryonic endothelial-like precursors divide asymmetrically to produce both hematopoietic and endothelial progenitors, or it is a specific population of VEC–positive cells that is already committed to generate the hematopoietic lineage (Rybtsov et al., 2011). We have now demonstrated that a specific CD31 subpopulation lacking c-kit and CD45 expression (called 31K−) generate hematopoietic cells dependent on Wnt/β-catenin signaling. Although VEC+CD41+ cells are shown to be the precursors of HSC in the mouse embryos (Rybtsov et al., 2011), we found that total CD31+CD41+CD45− sorted cell population was not affected by Wnt/β-catenin activation when cultured on stromal cells (unpublished data). However, it still remains possible that the CD41+ population inside the 31K− is the one that responds to Wnt/β-catenin.

Understanding the peculiarities that distinguish AGM and BM HSC formation is of crucial importance for future clinical applications, such as generation of hematopoietic cells from ESCs. Several protocols have been successfully developed to produce different cell types and tissues from ESCs but generation of long-term repopulating HSCs have not yet been achieved. Some efforts have been made to elucidate the putative role of Wnt/β-catenin in blood formation from ESCs, and it has been shown that it potentiates flk1+ hemogenic cell formation in both human (Woll et al., 2008) and mouse (Nostro et al., 2008) systems. However, what the effect will be of inducing β-catenin on HSC generation is not totally predictable. In this sense, it was shown that constitutive activation of β-catenin results in deleterious effects on HSC self-renewal (Kirstetter et al., 2006; Scheller et al., 2006; Renström et al., 2009; Lane et al., 2010). Our results demonstrate that transient activation of β-catenin in AGM explants, in contrast to APC mutations, does not impair HSC self-renewal, similar to in vivo inoculation of a GSK3β inhibitor in adult mice (Trowbridge et al., 2006). In summary, β-catenin activity is required in a dose- and time-dependent manner to preserve the functionality of AGM-derived HSCs, which is relevant information for future generation of functional HSCs from ESCs.

**MATERIALS AND METHODS**

**Animals.** CD1 or C57Bl6/J (CD45.2) embryos were staged by somite counting: E10.5, 31–40 sp; and E11.5, 42–50 sp. The detection of vaginal plug (Fig. S5 A) was designated as 0.5. TOPGAL mice (strain name: STOCK Tg(Fos-LacZ)TOPGAL). 34Efs/J;DasGupta and Fuchs, 1999), β-actin-GFP mice (strain name: C57BL/6-Tg(CAG-EGFP)1Osb/J), R26R-YFP mice (strain name: B6.129X1-Gt(ROSA)26Sor(LacZ,Cre)) (VEC-Cre mice (strain name: B6.Cg-Tg(Cdh5-cre)1Ala/J; Alva et al., 2006), and β-catenin fl/fl mice (strain name: Ctnnb1tm1Jak; Brauth et al., 2001) were purchased from The Jackson Laboratory. All mice were obtained in the C57Bl/6J background, except for TOPGAL mice which were bred in the CD1 background. The ratio of inheritance of the β-catenin fl/fl alleles in the VEC-Cre+ background was different from the Mendelian frequency expected. A two-tailed χ² analysis showed that the observed ratios
of +/+ to fl/+ to fl/fl were significantly different from that expected in the adult mice (P < 0.0001). Vav1-CRE mice (CD57B/6J background) have been previously described (Staffeld and Graf, 2008). C57Bl/6J (CD45.2 or CD45.1) mice were used for transplantation experiments. Mice and embryos were all genotyped by PCR or under the UV microscope (GFP lines). Animals were kept under pathogen-free conditions and experimental procedures approved by the Parc de Recerca Biomèdica de Barcelona (PRBB) Animal Care Committee and Government of Catalonia (Decree 214/1997).

Quantitative RT-PCR. Total RNA was extracted using RNeasy Midi C-kit (QIAGEN). RNA quality was assessed on agarose gel and quantified by Nano-Drop1000 (Thermo Fisher Scientific). cDNA was obtained with RT First Strand cDNA Synthesis (GE Healthcare) according to the manufacturer's instructions. Real-time PCR was performed in triplicate on the Light Cycler 480 (Roche) and with SYBR Green (Applied Biosystems). The primers used for SYBR Green detection are:

- GATGTCACGCACGATTTC-3
- CATTTTCCG-3
- TGTAAGCAGT -3
- GAGAGCAGAGCCC-3
- GAGGCAGAGGCCC-3
- LEFI (5'-CTCTACATCCATCCTAGCCGGCAGGA-3')
- 5'-TGAGGCTTCACGTGCATTAG-3'

Embryos or tissues were fixed overnight in 4%

Hemato poetic colony assay. 2 × 10⁶ cells from fresh AGMs, 2.5 × 10⁶ cells from FL, 3.5 × 10⁶ cells from AGM explants, or 1.5 × 10⁶ cells from liquid cultures were plated in M-3434 MethoCult medium (STEMCELL Technologies). After 7 d, the presence of hematopoietic colonies was scored under a microscope (CK2; Olympus).

Flow cytometry analysis and cell sorting. Cells were stained for 30 min with different antibodies. Antibodies used were CD31, CD45, and CD117 (c-kit; BD). Ter119 (BD) was used to exclude erythroid cells. DAPI staining was used to determine apoptosis. For cell cycle profile determination, pools of two disrupted AGMs were incubated in 8 µl Hoechst 33342 for 1 h in 10% FBS in PBS at 37°C. Flow cytometry analysis was performed on a FACS-Calibur or LSRII (BD). Cell sorting was performed on a FACSVantage or FACS Aria (BD). Purity of sorted populations was analyzed when enough cells were collected (Fig. S4). All data were analyzed with Flowjo software (Tree Star).

Immunofluorescence. Embryos or tissues were fixed overnight in 4% paraformaldehyde (Sigma-Aldrich) at 4°C, frozen in Tissue-Tek (Sakura), and sectioned (7 µm). Slides were fixed with ethanol at −20°C for 5 min and block-permeabilized in 1% FBS, 0.3% Surface-AmpX100 (Thermo Fisher Scientific), and 5% nonfat milk in PBS at 90 min at 4°C. Primary antibodies were used at the following concentrations: anti-nonphosphorylated β-catenin at 1:1,500 (Millipore), anti-CD31 at 1:50 (BD), anti-ckit at 1:50 (BD), anti-β-galactosidase at 1:3,000 (Molecular Probes), and anti-GFP at 1:500 (Takara Bio Inc.) in 10% FBS and 5% nonfat milk in PBS overnight at 4°C. Sections were stained with HRP-conjugated goat anti–rabbit (Dako), HRP-conjugated rabbit anti–rat (Dako), or HRP-conjugated rabbit anti–mouse (Dako) at 1:100 for 90 min and developed using the tyramide amplification system TSA-Plus Cyanine3/Fluorescesin System (PerkinElmer). TOPRO-3 or DAPI were used for nuclear staining and mounted in Vectashield medium (Vector Laboratories). Cells were counted in five different randomly selected sections.

Primary and secondary transplantation assays. Cells were transplanted into adult recipients as previously described (Medvinsky and Dzierzak, 1996). In brief, recipient mice were irradiated at 8.5 Gy yr irradiation (IBL437-C irradiator) and cells were co-injected intravenously with the support of 2 × 10⁶ spleen cells. Unless indicated, all AGM transplantations were performed with cells from one AGM explant and designated as 1 ee. Chimerism was tested at 4 and 16 wk after transplantation as percentage of donor cells (GFP) or CD45.1/CD45.2. Mice demonstrating ≥25% donor-derived multilineage chimerism after 16 wk were considered reconstituted. For limiting dilution experiments, 0.5 ee (50% of an AGM explant) or 0.25 ee (25% of an AGM explant) was used. In the latter experiments, cells were co-injected with 2 × 10⁶ spleen cells as a support and 2 × 10⁶ BM cells. When animals were sacrificed (after 16 wk), reconstitution was measured in PB and BM. For secondary transplantations, 7 × 10⁶ cells from each primary recipient were intravenously injected. The contribution to the different lineages of the transplanted cells was measured by flow cytometry with specific antibodies: CD3, B220, Ter119, Mac1, and Gr1 (mouse lineage panel; BD).

Microarrays. CD31 ’ckit’ CD45− and CD31 ’ckit’ CD45+ cells were directly sorted on LRT medium from E11.5 AGM from three independent experiments. RNA was obtained and assessed using Bioanalyzer 2100 (Aglent Technologies). Microarray expression profiles were obtained using the GeneChip Mouse Gene 1.0 ST array (Affymetrix) and the GCS3000 platform (Affymetrix). After hybridization, the array was washed, stained, and finally scanned to generate CEL files for each array. Data analysis was performed in R (version 2.11.1) with packages aroma.affymetrix, Biobase, Affy, limma, and genefilter. Ingenuity Pathway Analysis (version 8.5; Ingenuity Systems) was used to perform functional analysis of the results. A heat map was built using matrix2png (Pavlidis and Noble, 2003). Data is available at GEO (GSE35395).

Statistical analysis. Student’s t test or parametric analysis of variance was used by applying a rank transformation on the dependent variable. The analysis was performed using SAS software (version 9.2; SAS Institute Inc., Cary, NC), and the level of significance was established at 0.05 (two-sided). P < 0.05 (**), P < 0.01 (***), and P < 0.001 (****) has been indicated in the figures or left unlabeled when did not reach significance P > 0.05.

Detection of deleted band from individual colonies by PCR. Colonies were picked, washed with PBS, and resuspended in 20 µl yas buffer (0.01 M Tris, 1466 Wnt/β-catenin activity in HSC development | Ruiz-Herguido et al.
Online supplemental material. Fig. S1 shows the purity determination in different fractions of the AGM after cell sorting and Fig. S2 contains a table with Mendelian ratios of expected β-catenin mutant embryos and mice and multiceage contribution of β-catenin WT and mutant cells. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20120225/DC1.

We thank Jessica Gonzalez and Blanca Luerna for technical assistance and all the laboratory members for helpful discussions. Thanks to Andrew McMahon (Roche Institute of Molecular Biology), Berta Altisina and Cristina Pujades (Pompeu Fabra University, Barcelona) for critical reagents and Ferran Torres for statistical analysis, Thomas Graf (Center for Genomic Regulation [CRG], Barcelona) for Vπ1-Cre mice and for critically reading this manuscript, and Oscar Fornas for Flow Cytometry support. Thomas Graf (Center for Genomic Regulation [CRG], Barcelona) for helpful discussions. Thanks to Andrew McMahon (Roche Institute of Molecular Biology), Berta Alsina and Cristina Pujades (Pompeu Fabra University, Barcelona) for critical reagents and Ferran Torres for statistical analysis, Thomas Graf (Center for Genomic Regulation [CRG], Barcelona) for Vπ1-Cre mice and for critically reading this manuscript, and Oscar Fornas for Flow Cytometry support.
