Abstract: Ceramic coatings containing hydroxyapatite (HA) were fabricated on a biodegradable Mg66Zn29Ca5 magnesium alloy through micro-arc oxidation by adding HA particles into the electrolytes. The phase composition and surface morphology of the coatings were characterized by X-ray diffraction and scanning electron microscopy analyses, respectively. Electrochemical experiments and immersion tests were performed in Hank’s solution at 37 °C to measure the corrosion resistance of the coatings. Blood compatibility was evaluated by in vitro blood platelet adhesion tests and static water contact angle measurement. The results show that the typical ceramic coatings with a porous structure were prepared on the magnesium alloy surface with the main phases of MgO and MgSiO3 and a small amount of Mg3(PO4)2 and HA. The optimal surface morphology appeared at HA concentration of 0.4 g/L. The electrochemical experiments and immersion tests reveal a significant improvement in the corrosion resistance of the ceramic coatings containing HA compared with the coatings without HA or bare Mg66Zn29Ca5 magnesium alloy. The static water contact angle of the HA-containing ceramic coatings is 18.7°, which is lower than that of the coatings without HA (40.1°). The in vitro blood platelet adhesion tests indicate that the HA-containing ceramic coatings possess improved blood compatibility compared with the coatings without HA. Utilizing HA-containing ceramic coatings may be an effective way to improve the surface biocompatibility and corrosion resistance of magnesium alloys.

Keywords: coating; magnesium alloy; hydroxyapatite; micro-arc oxidation; corrosion resistance; blood compatibility

1. Introduction

Traditional permanent implants consisting of stainless steel, titanium and its alloys are important in the field of metallic implant materials for their maintaining mechanical integrity and good biocompatibility during the bone healing period [1]. However, metallic materials may cause the release of toxic corrosion products [2,3] and allergens [4,5]; it need a second surgery for implant removal after the healing of damaged tissues. As a result, biodegradable implants for biomedical application have attracted great attention in recent years [6–8]. Common biodegradable implants are made of polymers with unsatisfactory mechanical strength [7,9,10]. Magnesium and its alloys are now becoming a priority due to their low density, high specific strength and good biocompatibility, especially their biodegradability and non-toxicity to the human body [11–13]. The elastic modulus of magnesium is approximately 45 GPa [14], which is similar to that of human bone (3–20 GPa); this avoids
stress shielding effects when implanted into the human body [15,16]. However, magnesium and its alloys are considerably active metals in chloride containing physiological environments including human body fluid or blood plasma [13]. Therefore, the severe corrosion and accelerated degradation rate of magnesium and its alloys have limited their biomedical application.

In general, the corrosion resistance of magnesium and its alloys can be improved by (i) tailoring the grain size [17,18] or the microstructure and texture [19] of the base material by alloying and (ii) forming coatings via surface treatments on the substrates to obtain protective ceramics, polymers or composite layers [20]. Considering the requirements of biocompatibility, Mg-Zn-Ca alloys are promising for implant applications due to the fact that elements of Mg, Zn, and Ca can not only improve the mechanical properties but also participate in metabolic processes. As the low solubility of many elements in magnesium, the alloying of magnesium has a limitation for application. Therefore, the surface treatments are of high significance. Chemical conversion coatings are common protective coatings on magnesium and its alloys, such as calcium phosphate-containing layer [21,22] and fluoride phosphate-containing layer [23,24], which are biodegradable coatings for biomedical applications. Ion implantation has also been conducted as a technique to improve the corrosion resistance of magnesium alloy. However, the improvements were not significant measured in NaCl solution or Hank’s solution, e.g., Al, Zr, or Ti ions implanted in AZ91 [25] and Ta ion in AZ31 alloy [26].

Micro-arc oxidation (MAO), also known as plasma electrolytic oxidation or anodic spark deposition, is a novel, promising surface treatment, which has been developed and applied to magnesium and its alloys [27–31]. This technique has become one of the most prospective surface treatments due to the good adhesion and corrosion resistance of ceramic coatings. However, the application of these coatings on biodegradable implant materials must be further confirmed.

Hydroxyapatite (HA, Ca\(_{10}\)(PO\(_4\)\(_6\))(OH)\(_2\)) is a naturally occurring mineral of calcium apatite and is used as a biomedical material. HA exhibits excellent biocompatibility and bioactivity due to its structural and chemical similarities to bone minerals [32–34]. HA coatings are degradable in physiological environment and show good early interaction between the implant and the tissue [35]. Much research has been done on the fabrication of HA coatings on magnesium and its alloys; preparation methods include electrodeposition [36–38], aerosol deposition [39], chemical solution deposition [40], sol-gel method [41], and other processes [42,43]. It should be pointed that the poor bonding strength, corrosion resistance, and inhomogeneity of simplex HA coatings still restrict their application.

To the best of our knowledge, only few studies have reported the preparation of coatings containing HA via MAO [44]. Therefore, in this paper, a research on fabrication a HA-containing coating has been made by method of MAO technique. The effects of HA particles added into the electrolyte solution on the surface morphology, thickness, and hardness of the coatings were determined. Properties, including corrosion resistance and blood compatibility, of the coatings with and without HA were also investigated.

2. Experimental

2.1. Preparation of the Coatings

High-purity (>99.9 wt %) of Mg, Zn, and Ca were melted under an argon atmosphere in an induction furnace to achieve magnesium alloy with a composition of Mg\(_{66}\)Zn\(_{29}\)Ca\(_{5}\) (in atomic percentage). The test specimen was a disc with a diameter of 14 mm and a thickness of 3 mm. Prior to MAO, the specimens were ground with SiC papers (from 150 to 2000 grits), and polished with Al\(_2\)O\(_3\) aqueous suspension to an average surface roughness of \(R_a = 0.8 \ \mu\)m. The specimens were then ultrasonically rinsed in acetone and ethanol, and finally dried using nitrogen.

The electrolyte solution for MAO, which mainly consisted of Na\(_2\)SiO\(_3\) (10 g/L), Na\(_3\)PO\(_4\) (3 g/L), NaOH (2 g/L), and Glycerin (10 mL/L) was prepared with deionized water. And various concentrations of HA powder with mean size of 0.5 \(\mu\)m were then added into the electrolyte.
The concentrations of HA added into the electrolyte were selected as 0, 0.2, 0.4, and 0.6 g/L. Note that the electrolyte should be ultrasonically oscillated for 10 min before MAO to ensure that the HA particles are well dispersed throughout the electrolyte.

As a device used for MAO, the equipment (WHD-30) was composed of a pulsed power supply, electrolytic bath, and stirring and cooling system that can automatically control electrolyte temperature to <40 °C. In our experiment, constant voltage mode was adopted and the electric parameters were fixed as follows: 400 V anodic voltage, 80 V cathodic voltage, 1500 Hz frequency, and 50% duty cycle. The MAO coatings were deposited on the magnesium alloy specimens for 5 min.

2.2. Characterization of the Coatings

The morphologies of the coatings were characterized by scanning electron microscopy (SEM, Hitachi S-3000N) coupled with an energy dispersion spectroscopy (EDS). The phase composition was characterized by X-ray diffraction (XRD, D8 Advance) with Cu Ka in scanning angles of 20°–70°.

The thickness and microhardness of the coatings were examined using an eddy-current coating thickness gauge (Minitest 600B) and micro Vickers equipment (HXD-1000TMC), respectively. Measurements were carried out for 10 times, and the average values were determined.

Electrochemical measurements were performed in Hank’s solution at 37 °C by using an electrochemical workstation (CHI 660D). Hank’s solution was synthesized in the laboratory and composed of 8 g/L NaCl, 0.40 g/L KCl, 0.10 g/L MgCl₂·6H₂O, 0.10 g/L MgSO₄·7H₂O, 0.14 g/L CaCl₂, 0.06 g/L Na₂HPO₄·2H₂O, 0.06 g/L KH₂PO₄ and 1 g/L glucose. The experimental set-up comprised a conventional three-electrode cell containing a working electrode, a platinum sheet as the counter electrode, and an Ag-AgCl electrode as reference. The area of the working electrode that was exposed in the solution was 1.54 cm². The potentiodynamic polarization curves of the samples were measured at a scan rate of 1 mV/s. Prior to each test, the specimen was immersed in the solution for 10 min to stabilize the open circuit potential (OCP).

The immersion corrosion tests were performed in Hank’s solution for 20 d at a constant temperature of 37 °C. Every day, the samples were removed from the solution, rinsed ultrasonically with deionized water, and then dried. An electronic balance (FA 1004) was used to weigh the mass before and after the immersion, and mass loss curves were obtained by calculating the relative mass loss rate.

The static water contact angles of the coatings were measured by a video optical contact angle measuring instrument (DSA 25) to study the wetting properties.

In vitro blood platelet adhesion test was investigated to identify the blood compatibility of the coatings. Platelet-rich plasma (PRP) was prepared by centrifuging the whole blood for 15 min at a rate of 1000 rpm. The samples with and without HA coatings were ultrasonically rinsed with ethanol and deionized water for 10 min, respectively. The samples were then dried and placed into culture plates. The PRP was dropped on the surface of the samples and incubated in an electro-heating standing-temperature cultivator (Thermo 3110) at 37 °C for 2 h. After incubation, the samples were rinsed thrice with normal saline to remove non-adherent platelets. The platelets that adhered on the samples were fixed in 2.5% glutaraldehyde solutions for 1.5 h at room temperature, and the samples were dehydrated in a gradient ethanol/distilled water mixture (50%, 60%, 70%, 80%, 90%, and 100%) for 10 min each and then dried in air for more than 48 h. The morphology and distribution of the platelets were observed by SEM. The platelet shape change was evaluated from high-magnification micrographs. At least 50 platelets were analyzed for each sample.

3. Results and Discussion

3.1. Microstructure, Thickness, and Micro-Hardness of the Coatings

Figure 1 shows the surface morphologies of the coatings formed at various concentrations of HA. One can see that the coatings are porous with a large number of lamellar, spherical pieces, presenting a
typical feature of MAO coating. It should be noted that HA additive may considerably influence the surface morphologies. Figure 1b,c display the morphology of the coating added with 0.2 and 0.4 g/L HA in the electrolyte, respectively. Interestingly, samples prepared in the electrolyte with HA exhibited fewer cracks, smoother surface, and smaller pore size compared with samples without additional HA, as shown in Figure 1a.

![Figure 1. Surface morphologies of coatings formed at hydroxyapatite (HA) concentrations of (a) 0; (b) 0.2; (c) 0.4; and (d) 0.6 g/L.](image)

The electrical conductivity of the HA-containing complex electrolyte slightly decreased after the addition of a small amount of insulating HA particles. The voltage distribution on the specimen became somewhat low. Thus, instantaneous breakdown energy was small, and the discharge channel was narrow. Furthermore, the HA particles may enter into the discharge channel with the HA-suspended complex electrolyte, which raises the dielectric breakdown potential of the growing oxide film, resulting in the formation of smooth surface morphology.

As HA concentrations were increased to 0.6 g/L, on the one hand, the original uniform pore-structure gradually disappeared and was accompanied by the appearance of few large holes; on the other hand, some deep penetrating cracks were generated, and a small amount of white, sintered granules adhered to the surface of the coatings, as evidenced in Figure 1d. Thus, the surface quality of the coating decreased as HA concentrations were increased. This observation may be due to the large number of insulating HA particles that may hinder the movement of conductive ions in the electrolyte, resulting in the decrease in both the electrochemical reaction rate and migration of charged particles in the solution. Moreover, in the HA-suspended complex electrolyte, extensive heat that was generated during the electrical breakdown process cannot be easily spread, decreasing the cooling capacity of molten material.

The XRD pattern of the HA-containing coatings is shown in Figure 2. The coating consists mainly of MgO, MgSiO$_3$, and a small amount of Mg$_3$(PO$_4$)$_2$ and HA. HA cannot be easily identified from the full spectrum because of its small amount. In the inset in Figure 2, some characteristic diffraction peaks of HA are presented, indicating that HA was incorporated into the coatings.
The average micro-hardness of the HA-containing coatings (0.4 g/L, hereinafter) was approximately 215.8 ± 5.3 HV, slightly higher than that of the coatings without HA additive (hereinafter referred as MAO coating) which was about 194.7 ± 4.8 HV. The hardness of the HA-containing coatings might be enhanced by some dispersed HA particles as the second phase within the coatings. The thickness of the HA-containing coatings was 13.5 ± 0.2 µm; as for the MAO coatings, the thickness was about 12.9 ± 0.2 µm. There was no obvious variation in the thickness which might be interpreted as the same electric parameters during the MAO process.

3.2. Effect of HA on the Corrosion Resistance of the Coatings

Figure 3 illustrates the mass loss curves of the coatings and Mg₆₆Zn₂₉Ca₅ alloy immersed in Hank’s solution at 37 °C for 20 d. When the bare Mg₆₆Zn₂₉Ca₅ alloy was soaked in Hank’s solution, corrosion occurred immediately on the surface due to the rapid dissolution of active Mg and Ca. However, the coated alloys both present a relatively slow mass loss rate compared with bare Mg₆₆Zn₂₉Ca₅ alloy. This result indicates that the coatings can effectively protect the substrate to avoid further corrosion.

The mass loss of the coatings tended to linearly increase at the early immersion stage (approximately 3 d), but subsequently slowed down. It is well known that there is a loose and porous layer on the surface of coatings [29]. The corrosion medium can easily permeate into the loose superficial layer and spread out, resulting in severe corrosion. With the increase of immersion time, the dense inner layer would prevent corrosive medium further permeation, which leads to a slow corrosion rate; on the other hand, the coating may achieve a self-protection by the corrosion products obtained via a spontaneous mineralization in Hank’s solution [45], resulting in a slow corrosion rate.
as well. The mass loss rate was much lower in the HA-containing coating than that in MAO coating. As previous analysis, few cracks and pores were found in the HA-containing coatings, which inhibited the permeation of the corrosion medium, leading to good corrosion resistance.

The measurement of the OCP changes with time (OCP-t) can be employed to understand the chemical stability and corrosion process that occurs on the sample surface. The recorded OCP-t curves of Mg$_{66}$Zn$_{29}$Ca$_5$ alloys after soaking in Hank’s solution for up to 3 h are plotted in Figure 4. All of the samples exhibited a similar trend in the evolution of OCP: the potentials moved rapidly toward the positive direction at the initial stage, and then OCP was slightly increased (bare alloy) or maintained constant (HA-containing coating, MAO coatings). The rapid increase in OCP at the initial stage of immersion indicates the formation of a certain kind passivation layer on the sample surfaces. The bare alloy, especially, requires more time to reach a stable potential, indicating a slow rate of establishing equilibrium between corrosion and protection. Commonly, more positive OCP implies that the alloy is comparatively more passive. Therefore, the electrochemical activity of different samples follows the order bare alloy > MAO > MAO + HA.

**Figure 4.** Evolution of open circuit potential in Hank’s solution at 37 °C as a function of exposure time for the coatings.

Figure 5 shows the potentiodynamic polarization curves of HA-containing coating, MAO coating, and bare Mg$_{66}$Zn$_{29}$Ca$_5$ alloy in Hank’s solution at 37 ± 0.5 °C. The corrosion potential ($E_{corr}$) and corrosion current density ($I_{corr}$) can be calculated from polarization curves through a software using the Tafel extrapolation method. The fitting results are listed in Table 1. Both coatings in Hank’s solution show good anti-corrosion property. The $E_{corr}$ of the coatings, e.g., HA-containing coating ($−1.215$ V) and MAO coating ($−1.263$ V), significantly increased in comparison with that of bare Mg$_{66}$Zn$_{29}$Ca$_5$ alloy ($−1.422$ V); the $I_{corr}$ of the coatings reduced remarkably with values of $6.138 \times 10^{-8}$ A·cm$^{-2}$ and $8.831 \times 10^{-7}$ A·cm$^{-2}$, respectively, manifesting better corrosion resistance than Mg$_{66}$Zn$_{29}$Ca$_5$ alloy.

**Table 1.** Fitting results of polarization curves for bare and coated alloy.

| Sample                      | $E_{corr}$/V | $I_{corr}$/A·cm$^{-2}$ |
|-----------------------------|--------------|------------------------|
| Bare alloy                  | $−1.422$     | $2.546 \times 10^{-4}$ |
| MAO coating                 | $−1.263$     | $8.831 \times 10^{-7}$ |
| HA-containing coating       | $−1.215$     | $6.138 \times 10^{-8}$ |

For the coatings, the $E_{corr}$ of the HA-containing coating presented 48 mV positively shift and the $I_{corr}$ decreased by about 1 order of magnitude compared with MAO coating, revealing an improvement in anti-corrosion property.
3.3. Effect of HA Particles on the Blood Compatibility of the Coatings

Figure 6 shows the effect of HA particles on the amount and shape of blood platelet adhesion of the coatings. It can be seen that less blood platelet counts were observed on the HA-containing coating compared with that of the MAO coating. Furthermore, the platelets on the MAO coating were unevenly dispersed, with some regions exhibiting higher platelet density than those on the HA-containing coating. Generally, the sample with less platelet density adhering on the surface indicates improved blood compatibility [46]. The SEM micrographs also provided information on the morphology of adhered platelets and their activation state. The platelets on the HA-containing coating were round or oval without pseudopodia-like protrusions. However, platelets on the MAO coating were spread as dendritic with one or more pseudopodia. These results indicate that the HA-containing coating possessed good blood compatibility.

Figure 6. SEM images of blood platelet adhesion on the (a,b) micro-arc oxidation (MAO) coating and (c,d) HA-containing coating.
Figure 7 shows the change in the static water contact angles of the coatings with and without HA particles. The water contact angle of the MAO coating was $40.6^\circ$ whereas that of the HA-containing coating decreased to approximately $18.7^\circ$, indicating that the HA-containing coating possessed improved hydrophilicity. Normally, the percentages of round platelets and the total number of adhering platelets are related to the degree of hydrophobicity: the more hydrophilic the surface is, the lower the number of platelets adhering to it and the smaller are the changes in platelet shape. The improved hydrophilicity causes a less tendency of absorption in the protein, blood platelet, and blood clotting factors and resulting improvement in the blood compatibility of implant material [47,48].

4. Conclusions

An HA-containing coating was fabricated on a biodegradable Mg$_{66}$Zn$_{29}$Ca$_{5}$ magnesium alloy via MAO. The XRD analysis showed that the coating consists mainly of MgO, MgSiO$_3$, and a small amount of Mg$_2$(PO$_4$)$_2$ and HA, indicating that the HA can be incorporated into the coating. The average micro-hardness of the HA-containing coating (0.4 g/L) was approximately 215.8 HV, which was slightly higher than that of the coating without HA additive (approximately 194.7 HV). The $E_{corr}$ of the HA-containing coating significantly increased, whereas the $I_{corr}$ was remarkably reduced compared with bare Mg$_{66}$Zn$_{29}$Ca$_{5}$, manifesting an improved corrosion resistance. Lesser count and uniformity of blood platelets were observed on the HA-containing coating compared with those of the MAO coating. The static water contact angle of the HA-containing ceramic coating was $18.7^\circ$, which was lower than that of the coating without HA ($40.1^\circ$), demonstrating an improved blood compatibility in one respect. The HA-containing ceramic coatings may be an effective way to simultaneously improve the surface biocompatibility and corrosion resistance of magnesium alloys.
