Abstract

Background: Leishmaniasis is a parasitic disease associated with extensive mortality and morbidity. The treatment for leishmaniasis is currently based on pentavalent antimonials and amphotericin B; however, these drugs result in numerous adverse side effects. Natural compounds have been used as novel treatments for parasitic diseases. In this paper, we evaluated the effect of (-)-epigallocatechin 3-O-gallate (EGCG) on \textit{Leishmania braziliensis} \textit{in vitro} and \textit{in vivo} and described the mechanism of EGCG action against \textit{L. braziliensis} promastigotes and intracellular amastigotes.

Methodology/Principal Finding: \textit{In vitro} activity and reactive oxygen species (ROS) measurements were determined during the promastigote and intracellular amastigote life stages. The effect of EGCG on mitochondrial membrane potential (ΔΨm) was assayed using JC-1, and intracellular ATP concentrations were measured using a luciferin-luciferase system. The \textit{in vivo} experiments were performed in infected BALB/c mice orally treated with EGCG. EGCG reduced promastigote viability and the infection index in a time- and dose-dependent manner, with IC50 values of 278.8 μM and 3.4 μM, respectively, at 72 h and a selectivity index of 149.5. In addition, EGCG induced ROS production in the promastigote and intracellular amastigote, and the effects were reversed by polyethylene glycol (PEG)-catalase. Additionally, EGCG reduced ΔΨm, thereby decreasing intracellular ATP concentrations in promastigotes. Furthermore, EGCG treatment was also effective \textit{in vivo}, demonstrating oral bioavailability and reduced parasitic loads without altering serological toxicity markers.

Conclusions/Significance: In conclusion, our study demonstrates the leishmanicidal effects of EGCG against the two forms of \textit{L. braziliensis}, the promastigote and amastigote. In addition, EGCG promotes ROS production as a part of its mechanism of action, resulting in decreased ΔΨm and reduced intracellular ATP concentrations. These actions ultimately culminate in parasite death. Furthermore, our data suggest that EGCG is orally effective in the treatment of \textit{L. braziliensis}-infected BALB/c mice without altering serological toxicity markers.

Introduction

Leishmaniasis is a parasitic disease that is caused by protozoa of the genus \textit{Leishmania} and is associated with extensive mortality and morbidity. This disease is endemic in 98 countries, mainly in tropical and subtropical regions, and affects more than 12 million people worldwide. Leishmaniasis has an annual incidence of approximately 1.3 million cases and a prevalence of approximately 350 million people living in endemic areas. The disease severity caused by various \textit{Leishmania} species varies widely, ranging from cutaneous and/or mucosal to visceral infection [1,2].

\textit{Leishmania braziliensis} is the most common \textit{Leishmania} species in the Americas and is the etiological agent of cutaneous and mucocutaneous leishmaniasis [3]. Currently, Leishmaniasis treatment is based on pentavalent antimonials and amphotericin B; however, these drugs are expensive, result in numerous adverse side effects, and exhibit variable efficacy [4–7]. Numerous natural compound screens have successfully identified novel treatments for parasitic diseases [8,9]. Extracts obtained from plants and pure compounds, such as certain types of flavonoids, have been reported to possess significant antiprotozoal activity with no side effects [10–13]. For example, (-)-epigallocatechin 3-O-gallate (EGCG) is the most abundant polyphenolic flavonoid constituent of green tea and has been reported to possess anti-infective effects against viruses, bacteria and various fungi [14], anticancer properties [15,16], proapoptotic activity [17] and antiproliferative effects on \textit{Trypanosoma cruzi} [18] and \textit{Leishmania amazonensis} [19]. Although the precise molecular mechanism of
EGCG Promotes Leishmanicidal Effects via ROS Production

Author Summary

Leishmaniasis is a parasitic disease that is endemic in 88 countries, primarily located in tropical and subtropical regions, that affects more than 12 million people worldwide. Leishmaniasis treatments are currently based on pentavalent antimonials and amphotericin B; however, these drugs result in numerous adverse side effects and variable efficacy. In addition, the drugs are expensive, and parasite resistance to these drugs has been observed. The lack of affordable therapy necessitates the development of novel antileishmanial therapies. We investigated the antileishmanial activity of EGCG in vitro and in vivo and described the mechanism of EGCG action against Leishmania braziliensis promastigotes and intracellular amastigotes. EGCG reduced promastigote viability and the infection index in a time- and dose-dependent manner with a selectivity index of 149.5. This effect was reversed by polyethylene glycol (PEG)-catalase, suggesting that ROS production is a mechanism of action in promastigotes and intracellular amastigotes. Additionally, EGCG reduced ΔΨm and intracellular ATP concentrations in promastigotes. Furthermore, EGCG treatment was also effective in vivo, demonstrating oral bioavailability and reduced lesion sizes and parasitic load (92% of reduction) without altering serological toxicity markers. Additional studies should be conducted to determine the ideal dose and therapeutic regimen.

Materials and Methods

Reagents

Schneider’s Drosophila medium, (-)-epigallocatechin 3-O-gallate (EGCG), fetal calf serum, penicillin, streptomycin, horseradish peroxidase, and RPMI 1640 medium were obtained from Sigma-Aldrich (St. Louis, MO, USA). Hydrogen peroxide, and RPMI 1640 medium were obtained from Sigma-Aldrich (St. Louis, MO, USA). Horseradish peroxidase, and RPMI 1640 medium were obtained from Sigma-Aldrich (St. Louis, MO, USA). horseradish peroxidase, and RPMI 1640 medium were obtained from Sigma-Aldrich (St. Louis, MO, USA). horseradish peroxidase, and RPMI 1640 medium were obtained from Sigma-Aldrich (St. Louis, MO, USA).

Parasites

L. braziliensis promastigotes (MCAN/BR/97/P142 strain) were grown at 26°C (pH 7.2) in Schneider’s Drosophila medium supplemented with 100 U/ml penicillin, 100 μg/ml streptomycin, 20% (v/v) heat-inactivated fetal calf serum and 2% sterile human urine. The parasite number was determined by direct counting using a Neubauer chamber.

Cell proliferation

L. braziliensis promastigotes (MCAN/BR/97/P142 strain) were seeded into fresh medium containing Schneider’s Drosophila medium (1.0 ml final volume) supplemented with 100 U/ml penicillin, 100 μg/ml streptomycin, 20% (v/v) heat-inactivated fetal calf serum and 2% sterile human urine either in the absence (10 μl PBS) or presence of various EGCG concentrations (10 μl; 62.5–500 μM). The cells were maintained for 72 h at 26°C. The cell density was estimated using a Neubauer chamber. The growth curve was initiated with 1.0×10⁶ cells/ml. The 50% inhibitory concentration (IC₅₀) was determined by logarithmic regression analysis using GraphPad Prism 5 (GraphPad Software, La Jolla, CA, USA).

Hydrogen peroxide production

Hydrogen peroxide production was measured using Amplex red and horseradish peroxidase (HRP) [25]. Promastigotes were treated for 72 h in the absence or presence of EGCG (62.5–500 μM). Cells were harvested and resuspended in HBSS. The cell number was obtained by counting using a Neubauer chamber. Promastigotes (2×10⁷ cells/mL) were incubated with HBSS containing 10 μM Amplex red reagent and 10 U/ml HRP. Digoxygenin (64 μM) was added to permeabilize the parasites. Fluorescence was monitored at excitation and emission wavelengths of 560 and 590 nm, respectively, in a spectrofluorimeter. Calibration was performed using known quantities of H₂O₂. Data are expressed as the fold increase in hydrogen peroxide production relative to the control.

Determination of mitochondrial membrane potential (ΔΨm)

The cationic probe JC-1 was used to determine the mitochondrial membrane potential (ΔΨm) as described [13]. Promastigotes (1×10⁶ cells/ml) were cultured for 72 h in the absence or presence of 62.5–500 μM EGCG. Cells were harvested and re-suspended in Hank’s Balanced Salt Solution (HBSS). The cell number was obtained via counting in a Neubauer chamber. Promastigotes (1×10⁷ cells/ml) were incubated with JC-1 (10 μg/ml) for 10 minutes at 37°C. After washing twice with HBSS, fluorescence was measured spectrophluorometrically at 530 nm and 590 nm using an excitation wavelength of 480 nm. The ratio of values obtained at 590 nm and 530 nm was plotted as the relative ΔΨm.

The mitochondrial uncoupling agent carbonyl cyanide p-trifluoromethoxyphenylhydrazone (FCCP; 20 μM) was used as a positive control.

Intracellular ATP concentration measurement

Intracellular ATP concentrations were measured in treated and untreated cells using a CellTiter-Glo luminescent assay (Promega), where the signal is proportional to the ATP concentration. Briefly, promastigotes were treated for 72 h in the absence or presence of EGCG (62.5–500 μM). The cultures were washed thrice, and the parasite concentration was adjusted to 1×10⁷ cells in 200 μl of PBS. A 50-μl aliquot of each sample was transferred to a 96-well plate and mixed with the same volume of CellTiter-Glo. The
plates were incubated in the dark for 10 min, and the bioluminescence was measured using a GloMax-Multi Microplate Multimode Reader (Promega). ATP concentrations were calculated from the ATP standard curve.

Leishmania-macrophage interaction assay

*L. braziliensis* promastigotes were washed with phosphate buffered saline (PBS). The number of promastigotes was determined by counting with a Neubauer chamber. In the control (absence of EGCG), the same volume of PBS (solvent of EGCG) was added to the growth medium. The values are presented as the mean ± standard error of three different experiments.

doi:10.1371/journal.pntd.0003093.g001

Viability assay

Peritoneal macrophages (2×10⁶ cell/ml) collected from Swiss mice (6–8 weeks old) were allowed to adhere in black 96-well tissue culture plates for 1 h at 37°C in a 5% CO₂ atmosphere. The non-adherent cells were removed by washes with RPMI 1640 medium, and the wells containing adherent macrophages were refilled with RPMI 1640 medium supplemented with 10% fetal bovine serum. Increasing EGCG concentrations (3 to 3000 μM) were added to the cell culture for 24 and 72 h. The medium was then discharged, and the macrophages were washed with RPMI 1640 medium. Alamar-Blue (10% v/v) was added for 12 h at 37°C in a 5% CO₂ atmosphere. The absorbance was measured at 570 nm with a spectrophotometer. IC₅₀ values were determined by logarithmic regression analysis using GraphPad Prism 5. The selectivity index was determined using the following equation: macrophage IC₅₀/intracellular amastigote IC₅₀, as described by Weniger et al. [26]. Peritoneal macrophages were lysed with 0.1% Triton X-100 and used as positive controls.

Figure 1. The effect of EGCG on *L. braziliensis* promastigotes. *L. braziliensis* was cultivated in Schneider’s Drosophila medium at 26°C for 72 h in the absence or presence of EGCG (62.5–500 μM). The number of parasites was determined by direct counting using a Neubauer chamber. In the control (absence of EGCG), the same volume of PBS (solvent of EGCG) was added to the growth medium. The values are presented as the mean ± standard error of three different experiments. doi:10.1371/journal.pntd.0003093.g001
Measurement of ROS levels in Leishmania-infected macrophages

Intracellular ROS levels were measured in promastigotes, non-Leishmania-infected macrophages and Leishmania-infected macrophages treated and untreated with EGCG. *L. braziliensis* promastigotes were washed with PBS and counted using a Neubauer chamber. The promastigotes were added to peritoneal macrophages collected from Swiss mice (6–8 weeks old) at a parasite ratio of 3:1, and the cells were plated in black 96-well tissue culture plates at a cellular density of $2 \times 10^6$ macrophages/ml. This mixture was then incubated for 3 h at 37°C in a 5% CO$_2$ atmosphere. The free parasites were removed by successive washes with PBS. For the non-*Leishmania*-infected macrophages, peritoneal macrophages were collected from Swiss mice (6–8 weeks old) and plated in black 96-well tissue culture plates at a cellular density of $2 \times 10^6$ macrophages/ml. The cells were incubated for 3 h at 37°C in a 5% CO$_2$ atmosphere. Non-*Leishmania*-infected macrophages and *Leishmania*-infected macrophages were incubated in the absence or presence of EGCG (12 μM) for 24 h followed by H$_2$DCFDA (20 μM) for 30 minutes at 37°C. The fluorescence was measured spectrofluorometrically at 530 nm using an excitation wavelength of 507 nm. For all measurements, the basal fluorescence was subtracted. The positive control was obtained by the addition of 20 units/ml glucose oxidase + 60 mM glucose for 20 minutes.

In vivo infection in the murine model

BALB/c mice (5/group) were maintained under specific pathogen-free conditions and then inoculated with stationary-phase *L. braziliensis* promastigote ($2 \times 10^6$ cells in 10 μl of PBS) intradermally in the right ear using a 27.5-gauge needle. The method of treatment was similar to previously described methods [27,28] and initiated 21 days following infection. EGCG (100 mg/kg/day) was diluted in PBS and administered orally once daily seven times a week until the end of the experiment (day 32) when the animals were euthanized. The control group was treated orally with sterile PBS. The positive control was treated with intraperitoneal injections of meglumine antimoniate (30 mg/kg/day) once daily seven times a week until the end of the experiment (day 32). The lesion sizes were measured twice a week using a dial caliper.

Parasite load quantification

The parasite load was determined 32 days post-infection using a quantitative limiting dilution assay, as previously described [29]. The infected ears were excised, weighed and minced in Schneider’s medium with 20% fetal calf serum. The resulting cell suspension was serially diluted. The number of viable parasites in each ear was estimated from the highest dilution that promoted promastigote growth after 7 days of incubation at 26°C.

Toxicology

The serum levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT) and creatinine in the infected BALB/c mice treated orally and intraperitoneally as described above were measured using laboratory colorimetric kits (Doles, Goiânia, Brazil).

Ethics statement

This study was performed in strict accordance with the recommendations of the Guide for the Care and Use of Laboratory Animals of the Fundação Oswaldo Cruz. The protocol was approved by the Committee on the Ethics of Animal Experiments of the Fundação Oswaldo Cruz (License Number: EW-7/10).
Statistical analysis

All experiments were performed thrice. The data were analyzed statistically using Student’s t-test and a one-way or two-way analysis of variance (ANOVA) followed by Bonferroni’s post-test using GraphPad Prism 5 (GraphPad Software, La Jolla, CA, USA). The results were considered significant when \( p \leq 0.05 \). The data are expressed as the mean ± standard error.

Results

The effect of (-)-epigallocatechin 3-O-gallate (EGCG) on *Leishmania braziliensis* promastigotes is dose-dependent

Initially, the effect of EGCG on *L. braziliensis* promastigotes was investigated. We incubated the parasites with varying EGCG concentrations (62.5–500 \( \mu \)M) for 72 h. EGCG decreased *L. braziliensis* promastigote viability in a dose-dependent manner \( (p<0.05) \) (Figure 1). The inhibitory effect was 80.7% with 0.500 mM EGCG, and the IC\textsubscript{50} was 278 \( \mu \)M.

EGCG promote generation of hydrogen peroxide in *L. braziliensis* promastigotes

EGCG induces hydrogen peroxide (H\textsubscript{2}O\textsubscript{2}) production in various biological contexts [30]. Therefore, we investigated whether EGCG-mediated H\textsubscript{2}O\textsubscript{2} generation in *L. braziliensis* promastigotes is a possible mechanism of cell death. EGCG treatment for 72 h increased H\textsubscript{2}O\textsubscript{2} generation in *L. braziliensis* in a dose-dependent manner \( (p<0.01) \) (Figure 2A). The ROS levels were 2.9-fold higher in *L. braziliensis* treated with 500 \( \mu \)M EGCG compared with the control. A linear correlation \( (R^2 = 0.975) \) between the percent inhibition of the infection index and EGCG-mediated H\textsubscript{2}O\textsubscript{2} production was observed (Figure 2B).

To confirm that the inhibitory effects of EGCG are mediated by H\textsubscript{2}O\textsubscript{2} production, we pre-incubated *L. braziliensis* promastigotes with polyethylene glycol (PEG)-catalase (500 U/ml), which catalyzes hydrogen peroxide to water and oxygen. (PEG)-catalase protected *L. braziliensis* from EGCG-mediated effects (Figure 3A) and reduced H\textsubscript{2}O\textsubscript{2} levels in EGCG-treated cells (Figure 3B).

**Figure 4. The effect of EGCG on mitochondrial membrane potential in *Leishmania braziliensis*.** *Leishmania braziliensis* was cultivated in Schneider’s Drosophila medium at 26°C for 72 h in the absence or presence of 62.5–500 \( \mu \)M EGCG. Promastigotes were labeled with the potentiometric probe JC-1 (10 \( \mu \)g/ml). The positive control was treated with FCCP (20 \( \mu \)M) for 20 minutes. In the control (absence of EGCG), the same volume of vehicle (PBS) was added to the growth medium. Dose-dependent alterations in relative \( \Delta \psi_m \) values are expressed as the ratio of the fluorescence measurements at 590 nm (for J-aggregate) versus 530 nm (for J-monomer). The data are expressed as the means ± standard errors of three different experiments. * indicates a significant difference relative to the control group \( (p<0.05) \); ** indicates a significant difference relative to the control group \( (p<0.01) \).

doi:10.1371/journal.pntd.0003093.g004
suggesting that H$_2$O$_2$ production is a possible mechanism for the induction of _L. braziliensis_ promastigote death.

**EGCG induces mitochondrial membrane potential ($\Delta \Psi_m$) depolarization in _Leishmania braziliensis_**

The parasite mitochondrial function was evaluated using JC-1, a cationic mitochondrial vital dye. This dye is lipophilic and concentrates in mitochondria in proportion to the membrane potential; increased dye accumulation is observed in mitochondria with greater $\Delta \Psi_m$. The spectrofluorometric data presented in Figure 4 indicate a marked dose-dependent decrease in the relative fluorescence intensity ($\Delta \Psi_m$ values) ($p<0.001$). These results indicate membrane potential depolarization in cells upon treatment with 62.5 to 500 $\mu$M of EGCG, and $\Delta \Psi_m$ was reduced by 68.4% upon treatment with 500 $\mu$M EGCG. Similarly, decreased relative fluorescence intensity values were also observed following treatment with 20 $\mu$M FCCP (88.7% reduction).

**EGCG impairs ATP production in _L. braziliensis_ promastigotes**

Given the effect on $\Delta \Psi_m$, we evaluated intracellular ATP concentrations in EGCG-treated parasites. EGCG reduced intracellular ATP levels in _L. braziliensis_ promastigotes in a dose-dependent manner ($p<0.001$). The intracellular ATP concentration was reduced by 84.6% in parasites treated with 500 $\mu$M EGCG for 72 h (Figure 5).

**Dose-dependent effect of EGCG on _Leishmania_-infected macrophages**

To determine the effects of EGCG on the interaction of _L. braziliensis_ with macrophage cells after parasite invasion, untreated promastigotes were allowed to interact with macrophages for 3 h. Then, the _Leishmania_-infected macrophages were incubated in the absence or presence of EGCG (3 $\mu$M, 6 $\mu$M, or 12 $\mu$M) for 24 (Figure 6A) and 72 h (Figure 6B). EGCG reduced the infection...
index in a time- and dose-dependent manner (p<0.01) with IC_{50} values of 3.7 and 3.4 μM, respectively. This inhibitory effect was equal to 73.0% and 94.9% with 12 μM after 24 and 72 h, respectively. The IC_{50} of EGCG against macrophages was 384.4 μM (data not shown) and 436.3 μM [19], demonstrating a selectivity index of 103.3 and 149.5 at 24 and 72 h, respectively.

ROS production contributes to EGCG-induced death in Leishmania-infected macrophages

EGCG possesses prooxidative properties [22–24]. To investigate whether the leishmanicidal effect of EGCG is due to intracellular amastigote ROS production, we measured ROS levels using the cell-permeable dye H_2DCFDA [31–34]. EGCG induces ROS production in Leishmania-infected macrophages, not non-infected macrophages. The ROS levels were increased 2.5-fold (p<0.05) in EGCG-treated (12 μM) Leishmania-infected macrophages compared with Leishmania-infected macrophages throughout the experiment (Figure 7). Given that glucose oxidase catalyzes the oxidation of D-glucose and generates H_2O_2, this enzyme was employed as a positive control. The addition of glucose/glucose oxidase resulted in increased ROS levels compared with the control (3.1-fold, compared with ROS levels in Leishmania-infected macrophages).

Previous studies suggest that EGCG induces H_2O_2 production, which may be linked to the cytotoxic effects of chemical treatments [22,24,35]. Thus, we tested H_2O_2 production in L. braziliensis-infected macrophages that were preincubated with polyethylene glycol (PEG)-catalase (500 U/ml). We determined that PEG-catalase protected L. braziliensis from EGCG-mediated inhibition (p<0.05) (Figure 8 panel A) and reduced ROS levels in Leishmania-infected macrophages treated with EGCG (p<0.05) (Figure 8B). EGCG treatment inhibited the intracellular amastigotes without any apparent cytotoxicity as evidenced by the intact cell morphology (Figure 8 C–F); the damage caused by increased ROS appeared to be selectively directed towards intracellular amastigotes.

In vivo effects of EGCG in BALB/c mice infected with Leishmania braziliensis

To assess the efficacy of EGCG in vivo, the ears of BALB/c mice were intradermally infected with 2x10^6 L. braziliensis promastigotes, and the mice were treated orally with EGCG (100 mg/kg/day). As shown in Figure 9A and 9B, the oral administration of EGCG reduced the lesion size compared with the control group (p<0.001).

Interestingly, EGCG oral treatment significantly reduced the parasite burden (92.1% of reduction; p<0.001) compared with the
control group (Figure 9C). However, no significant differences in lesion size (60.5% and 64.0%, respectively; Figure 9 panel A inset and panel B) and parasite load (92.1% and 94.7%, respectively; Figure 9 panel C) were observed between the infected mice treated with EGCG or meglumine antimoniate. Furthermore, no significant differences in serum ALT (Figure 9D), AST (Figure 9E) and creatinine (Figure 9F) levels were observed between mice treated with EGCG and untreated mice (the control group).

Discussion

EGCG is the most abundant and widely studied flavonoid. EGCG has generated considerable interest as a pharmaceutical compound due to its wide range of therapeutic activities [16,36], such as those exhibited against *T. cruzi* [18,37]. In the present study, we demonstrated the effect of EGCG *in vitro* on *L. braziliensis* promastigotes and intracellular amastigote forms and *in vivo* on *L. braziliensis*-infected BALB/c mice. In addition, we describe the EGCG mechanism against *Leishmania braziliensis* promastigotes and intracellular amastigotes.

EGCG inhibited *L. braziliensis* promastigote viability in a dose-dependent manner, achieving 80.7% inhibition upon treatment with 500 µM EGCG. These results demonstrate the antileishmanial activity of EGCG against *L. braziliensis* promastigotes. Similar dose-dependent EGCG activities were observed in the promastigote and intracellular amastigote forms of *L. amazonensis* [19,20]. The trypanocidal effects of EGCG against epimastigotes, amastigotes and trypomastigotes have been reported [18,37].

The treatment of intracellular amastigotes with EGCG resulted in a time- and dose-dependent inhibitory effect, with IC50 values of 3.7 and 3.4 µM at 24 and 72 h, respectively, and a selectivity index of 103.3 and 149.5 at 24 and 72 h, respectively. The biological efficacy of a drug is not attributed to cytotoxicity when the selectivity index $\geq 10$ [26,38]. These results demonstrate the antileishmanial activity of EGCG against *L. braziliensis* amastigotes.
The antileishmanial potency of EGCG was greater than that of miltefosine, which has been successfully used for the treatment of New World leishmaniasis [39–42], with an IC50 value of 5.40 μM at 72 h for L. braziliensis and a selectivity index of 17.2 [42].

It has been demonstrated that the effectiveness of inhibitor compounds may depend on the developmental stage of the parasite. For instance, Santos et al. [43] demonstrated that L. amazonensis amastigotes developing within macrophages are more sensitive to HIV aspartyl peptidase inhibitors than promastigotes developing in culture medium, which may explain why promastigotes were less susceptible to EGCG than intracellular amastigotes.

Another possible explanation for the distinct action of EGCG on promastigotes alone and on amastigotes in an intracellular environment is the idea that macrophages could accumulate higher levels of EGCG. Accordingly, it was shown in L. infantum that lower concentrations of HIV-1 protease inhibitors are necessary to exert a pronounced effect against intracellular amastigotes compared to axenic amastigotes [44].

ROS are generated in cells to fight pathogenic infections. ROS are also generated in response to various drugs. This mechanism is the basis of various antiprotozoal medications used to combat parasites in infected cells. Importantly, the ability of a drug to generate ROS, which result in the destruction of cellular macromolecular components, can be modulated to derive maximal effects [45]. In this study, EGCG increased H2O2 generation in promastigotes in a dose-dependent manner, and H2O2 production directly correlated with the percent inhibition of viable promastigotes. Our results are consistent with results from Fonseca-Silva et al., who previously demonstrated that quercetin, the most common flavone in the human diet, induces ROS production in a dose-dependent manner in L. amazonensis [13].

In amastigotes from Leishmania-infected macrophages, EGCG increased ROS generation after 24 h, the shortest time resulting in infection index reduction (73% reduction), suggesting that increased ROS could be specific to intracellular amastigotes.

The exposure of L. amazonensis-infected macrophages, EGCG increased ROS generation after 24 h, the shortest time resulting in infection index reduction (73% reduction), suggesting that increased ROS could be specific to intracellular amastigotes. The exposure of L. amazonensis-infected macrophages to diethylthiocarbamate (DETC) [28] and quercetin [34] has been shown to increase superoxide anion and reactive oxygen species levels, respectively. These effects subsequently induce a severe reduction in the number of intracellular parasites and demonstrate the efficacy of ROS as an antimicrobial agent against intracellular parasites.

PEG-catalase significantly reduced EGCG-induced promastigote and intracellular amastigote death without apparent cytotoxicity to the EGCG-treated macrophages. Therefore, we postulate that EGCG-induced leishmanicidal activity occurs, at least in part, through ROS selectively directed towards promastigotes and intracellular amastigotes, thereby potentially altering the cellular redox status.

Figure 9. In vivo leishmanicidal effect of EGCG in L. braziliensis-infected BALB/c mice. The right ears of the mice were infected intradermally with 2 × 10^6 L. braziliensis promastigotes. Panel A: Lesion development in the animals administered oral EGCG (100 mg/kg/day; closed square) or the control group orally administered sterile PBS (vehicle of EGCG; closed circle) once a day seven times a week. Arrow represents the initiation of treatment. Inset: Lesion development in animals that were administered oral EGCG (100 mg/kg/day; closed square) and the control groups, which were orally administered sterile PBS (vehicle; closed circle) or treated with intraperitoneal injections of meglumine antimoniate (30 mg/kg/day; open triangle) once a day seven times a week. The arrow represents the initiation of treatment. Panel B: Macroscopic evaluation of lesions (arrowhead) in untreated mice (left column), EGCG-treated mice (medium column), and meglumine antimoniate-treated mice (right column) at the end of the experiment (day 32). The arrowhead represents the lesion. Panel C: Parasite burden of L. braziliensis-infected BALB/c mice untreated or treated with EGCG (100 mg/kg/day) or meglumine antimoniate (30 mg/kg/day). Ear parasite loads were determined via a limiting dilution assay. Panels D–F: Toxicity parameters for the kidneys and liver. At the end of experiment, the mice were euthanized, and serum samples were collected for colorimetric determination of aspartate aminotransferase (AST) (panel D), alanine aminotransferase (ALT) (panel E), and creatinine (panel F) concentrations as parameters of liver and kidney toxicity. Data are expressed as the mean ± standard error, n = 5 ears. *** indicates a significant differences relative to the control group (p < 0.001). Mitochondria are essential cellular organelles that play a central role in energy metabolism. Mitochondria are critical for the survival of all cells. Maintenance of mitochondrial membrane potential ($\Delta \Psi_m$) is vital for this metabolic process and cell survival [46,47]. Studies have demonstrated that variations in $\Delta \Psi_m$ induced by drugs are associated with cell survival in T. cruzi [12,48], Leishmania donovani [47] and L. amazonensis [13,20,49]. We demonstrated altered $\Delta \Psi_m$ in the EGCG-treated promastigotes. The collapse of $\Delta \Psi_m$ results from ROS release induced by chemical agents [50,51]. Therefore, we suggest that EGCG exerts its antileishmanial effect on L. braziliensis promastigotes via H$_2$O$_2$ production followed by a loss of that EGCG exerts its antileishmanial effect on L. braziliensis in infection is unavailable. BALB/c mice infected with L. braziliensis should be conducted to demonstrate this inhibition.

Mitochondria are responsible for respiratory and oxidative phosphorylation in eukaryotes, including trypanosomes. Mitochondria provide ATP through respiratory-coupled oxidative phosphorylation [52]. A decrease in $\Delta \Psi_m$ suggests increased proton permeability across the inner mitochondrial membrane, thereby decreasing ATP synthesis and resulting in parasite death. We also demonstrated that EGCG reduced intracellular ATP concentrations, thereby promoting a global breakdown in the parasite metabolism.

The oxidative imbalance that leads to a decrease in $\Delta \Psi_m$, thus reducing the intracellular ATP concentration, could occur through the reduction of trypanothione reductase (TR) activity. TR is an enzyme that participates in ROS detoxification of trypanosomatids and could be inhibited by EGCG. This trypanothione-dependent pathway is unique to the parasite and absent in the mammalian host [53,54]. This effect has been demonstrated by the treatment of T. cruzi with eupomatoidin-5 [55]. Further studies should be conducted to demonstrate this inhibition.

To date, an ideal experimental model for Leishmania braziliensis infection is unavailable. BALB/c mice infected with L. braziliensis are resistant for respiratory and oxidative phosphorylation in in vivo studies should be conducted to demonstrate this inhibition.

EGCG decreased the lesion size and parasite load without compromising the overall health of the infected mice. These results are encouraging and suggest that EGCG should be further studied as a potential leishmaniasis chemotherapy. Additionally, studies should be conducted to determine the ideal dose and therapeutic regimen.

In conclusion, our study suggests that EGCG displays leishmanicidal effects against the promastigote and amastigote forms of L. braziliensis. As part of the EGCG mechanism of action, ROS production decreases $\Delta \Psi_m$ and reduces intracellular ATP concentrations, thereby promoting parasite death. Furthermore, our data suggest that EGCG is orally effective in the treatment of L. braziliensis-infected BALB/c mice without altering serological toxicity markers.
