ABSTRACT

We find evidence that the mass \( M_{\text{BH}} \) of central supermassive black holes (SMBHs) correlates with the velocity dispersion \( \sigma_{\text{GC}} \) of globular cluster systems of their host galaxies. This extends the well-known \( M_{\text{BH}} - \sigma_{\text{sph}} \) relation between black hole mass and velocity dispersion of the host spheroidal component. We compile published measurements of both \( M_{\text{BH}} \) and \( \sigma_{\text{GC}} \) for a sample of 13 systems and find the relation

\[
\log(M_{\text{BH}}) = \alpha + \beta \log(\sigma_{\text{GC}}/200) \quad \text{with} \quad \alpha = 8.63 \pm 0.09 \quad \text{and} \quad \beta = 3.76 \pm 0.52
\]

We also consider blue (metal-poor) and red (metal-rich) globular clusters sub-populations separately and obtain a surprisingly tight correlation using only the velocity dispersion \( \sigma_{\text{GC}}^{\text{red}} \) of the red clusters with \( \alpha = 8.73 \pm 0.09 \) and \( \beta = 3.84 \pm 0.52 \) and an intrinsic scatter \( \varepsilon_0 = 0.22 \) dex compared to \( \varepsilon_0 = 0.27 \) dex for the \( M_{\text{BH}} - \sigma_{\text{sph}} \) of our sample. We use this \( M_{\text{BH}} - \sigma_{\text{GC}}^{\text{red}} \) relation to estimate the central black hole mass in five galaxies for which \( \sigma_{\text{GC}}^{\text{red}} \) is measured.

Key words: black hole physics – galaxies: evolution – galaxies: nuclei – galaxies: star clusters: general – galaxies: fundamental parameters – globular clusters: general

1 INTRODUCTION

It has been known for more than a decade that supermassive black holes (SMBHs) reside at the centre of many galaxies (Kormendy & Richstone 1995) and that their mass correlates with various properties of their host galaxies, for example with the spheroid luminosity (Magorrian et al. 1998), the spheroid velocity dispersion \( \sigma_{\text{sph}} \) (Ferrarese & Merritt 2000 and Gebhardt et al. 2000, see also Gultekin et al. 2009; hereafter G09), the spheroid mass (Magorrian et al. 1998; Marconi & Hunt 2003) and the kinetic energy of random motions (Peeti & Mancini 2009). Recent extension of these correlations to barred galaxies and pseudo-bulges (Hu 2008; Graham 2008a,b; Graham et al. 2011) as well as galaxies hosting nuclear star clusters (Ferrarese et al. 2002; Graham 2012) has also been proposed. In addition, a new correlation between the mass of SMBHs and the observed total number of globular clusters of their host galaxies has been discovered (Barber & Tremaine 2010, hereafter BT10, Harris & Harris 2011, see also Snyder, Hopkins, & Hernquist 2011). The physics underlying these observations is not fully understood, but it is widely believed that feedback processes are responsible for such correlations (Silk & Rees 1998). It is not known whether these relations evolve with time or are primordial and have been set at the time of formation of the SMBHs and galaxies (Di Matteo, Springel, & Hernquist 2003; Cox et al. 2006; Hopkins et al. 2006; Hopkins, Murray, & Thompson 2006, Volonteri & Natarajan 2008). Furthermore, the physical scale at which the feedback is effective is still not clear. Studies emphasising that black hole mass is coupled to the dark matter (DM) potential rather than the spheroid (Ferrarese 2002; Booth & Schaye 2010; Volonteri, Natarajan, & Gultekin 2011) seem to indicate that feedback processes operate on large scales even though Kormendy & Bender (2001) argue that there is no direct relation between DM halos and central black holes. Better and more data, extending to higher redshifts, shall shed more light on these questions.

In this paper we provide evidence that the classical \( M_{\text{BH}} - \sigma_{\text{sph}} \) relation between black hole mass and spheroid velocity dispersion is also working with the velocity dispersion of globular cluster (GC) systems. We use the published data for the velocity dispersion \( \sigma_{\text{GC}} \) of the GC systems and the estimated black hole mass in 13 galaxies. We then study separately the two sub-populations: blue, metal-poor GCs and red, metal-rich and younger GCs which are generally closer to the centre of the galaxy. We show that the correlation degrades from the red to the blue GCs sub-population.

This paper is organised as follows. In Section 2 we present the data. The correlation between the mass of SMBHs and the velocity dispersions of the GC systems of their host galaxies is presented in Section 3. The red and blue sub-populations are studied separately in Section 4. In Section 5 we estimate the black hole mass for 5 galaxies and conclude in Section 6.
2 THE DATA

We have found 19 galaxies for which measurements of the line-of-sight velocity dispersion of the GC system are known. Thirteen of these are accompanied by the estimate of the mass of their central black hole. These galaxies are presented in Table 1. To our knowledge, the mass of the central black holes have not yet been determined for the six other galaxies for which we have the velocity dispersion of the GC system: NGC 1407 (Romanowsky et al. 2009), NGC 3923 (Norris et al. 2012), NGC 4494 (Foster et al. 2011), NGC 4636 (Lee et al. 2010), LMC (Freeman 1993) and M33 (Schommer et al. 1999; Chandar et al. 2002).

2.1 Velocity dispersion of globular cluster systems

Galaxies for which we found measurements of $\sigma_{GC}$ as well as $\sigma_{GC}^2$ and $\sigma_{GC}^{blue}$ are listed in Table 1 along with the corresponding references. Whenever available, we use the value of $\sigma_{GC}$ corrected for the global rotation of the GC system. Comments on individual systems are given below:

- **NGC 1399** - We use the results of Richtler et al. (2004) which give $\sigma_{GC}$ for all GCs and for both red and blue sub-populations. Schuberth et al. (2010) give detailed results for different sub-samples and different distances which are in general not too different from Richtler et al. (2004).

- **NGC 5031 (M81)** - Results have been obtained separately by Perelmutter et al. (1993), Schroder et al. (2002) and Nantais & Huchra (2010). We use the values given by Nantais & Huchra (2010) which are consistent with the other groups. Measurement uncertainties in $\sigma_{GC}$, $\sigma_{red}^{GC}$ and $\sigma_{blue}^{GC}$ were provided by Nantais (2012).

- **NGC 4594 (M104)** - The value of $\sigma_{GC}$ is taken from Bridges et al. (2007). They also measured $\sigma_{red}^{GC}$ and $\sigma_{blue}^{GC}$ but do not give the corresponding error bars. Consequently, we do not include M104 in our best-fit estimate when treating red and blue GCs separately.

- **MW** - Zinn (1996) gives $\sigma_{GC}$ for three groups of GCs lying approximately around the direction of the galactic centre. The corresponding line-of-sights are therefore nearly parallels and we can treat the measured radial velocities as projection on a single line-of-sight similarly to what is done for external galaxies. The three groups are metal-poor (blue), red clusters lying between 2.7 to 6 kpc from the galactic centre, and very metal-rich disc clusters. We choose the dispersion of the red clusters ($\sigma_{red}^{GC} = 61 \pm 10$ km s$^{-1}$) to compare with the dispersion of red GCs in other galaxies. We note that a similar value was found by Harris (1999) for metal-rich clusters lying in the range 4 – 9 kpc. Concerning the metal-poor clusters, we retain the value $\sigma_{blue}^{GC} = 120 \pm 14$ km s$^{-1}$ given by Harris (1999). However, we point out that comparison with external galaxies is not straightforward in this case since we can no longer consider the projection of cluster velocities on a single line-of-sight.

2.2 Mass of central black holes

The mass of central black holes in 9 out of the 13 galaxies in our sample, namely NGC 224, NGC 1399, NGC 3031, NGC 3379, NGC 4486, NGC 4594, NGC 4649, NGC 5128, NGC 7457 and MW have been studied and analysed by G09. To avoid systematic errors and for general consistency, we have decided to use these results although we are aware that other values also exist in the literature. For NGC 1399 and NGC blue 5128, G09 give two possible values for the mass. We follow their procedure and include both values with a weight of 1/2 when performing the linear fit, a method also used by BT10. For the Milky Way, we use $M_{BH} = 4.3 \times 10^6 M_\odot$ from Gillessen et al. (2009) (G09 give $M_{BH} = 4.1 \times 10^6 M_\odot$).

For NGC 4636 only two upper limits for $M_{BH}$ are given in Beifiori et al. (2009). We do not incorporate these values in the determination of the parameters of the relation. However, we still include a posteriori NGC 4636 in all of the presented figures by taking the mean of the values found in Beifiori et al. (2009) as an upper limit for $M_{BH}$.

3 THE $M_{BH} - \sigma_{GC}$ RELATION

In Figure 1 we plot the central black hole mass $M_{BH}$ versus the velocity dispersion $\sigma_{GC}$ of the GC system with the error bars (see Table 1). To facilitate comparison with the previous works of G09, we use the same presentation. We assume a relation of the form $\log (M_{BH}/M_\odot) = \alpha + \beta \log (\sigma_{GC}/200$ km s$^{-1}$). The parameters of the relation are calculated by the $\chi^2$-minimisation technique of Tremaine et al. (2002) using the IDL MPFITEXY routine (Williams, Bureau, & Cappellari 2010) which includes error bars in both $M_{BH}$ and $\sigma_{GC}$ (weighted fit) and allows the determination of the intrinsic scatter $\epsilon_0$ in $M_{BH}$ at fixed
\[ \beta = 3 \]

\[ \alpha \]

\[ \varepsilon_0 \]

\[ \sigma_{GC} \]

The MPFITEXY routine depends on the MPFIT package [Markwardt 2009]. We also carry out a standard linear least-squares fit without taking into account error bars (unweighted fit) for comparison. We obtain \( \alpha = 8.63 \pm 0.09 \) and \( \beta = 3.76 \pm 0.52 \) for the weighted fit (Table 2). For the full sample used by G09, these values are \( \alpha = 8.12 \pm 0.08 \) and \( \beta = 4.24 \pm 0.41 \). The slope of the relation between \( M_{BH} \) and \( \sigma_{GC} \) is consistent with the one obtained by G09. However, for the same \( M_{BH} \) the velocity dispersion of the GC system is systematically smaller than that obtained for the spheroid. The intrinsic scatter we found is \( \varepsilon_0 = 0.27 \). As a comparison, we have examined the usual \( M_{BH} - \sigma_{sph} \) relation using the galaxies in our sample with values of \( \sigma_{sph} \) taken from G09 and obtained a similar value of \( \varepsilon_0 = 0.27 \) with the same fitting procedure. Thus, it seems that, for the limited number of galaxies in our sample, \( M_{BH} \) correlates equally well with either \( \sigma_{sph} \) or \( \sigma_{GC} \).

**4 RELATION FOR BLUE AND RED GLOBULAR CLUSTER SYSTEMS**

GCs are usually divided into two sub-populations with different features: the metal-poor GCs which are generally older and have a shallower number density profile than the metal-rich GCs which consist mostly of younger objects associated with the spheroid and lying closer to the centre. The two sub-populations are often referred to as the blue

**Figure 2.** Mass \( M_{BH} \) versus velocity dispersion \( \sigma_{GC}^{\text{red}} \) of the red, metal-rich globular cluster system for galaxies in our sample. As in Figure 1, circles are data points included in the fitting procedure whereas squares are systems which do not contribute to the best-fit relation, namely NGC4594 and NGC4636. The lines have the same meaning as in Figure 1.
and red GCs sub-populations respectively. Here, we examine separately the $M_{\text{BH}} - \sigma_{\text{GC}}$ relation of these two categories. Concerning the red GCs, measurements of $\sigma_{\text{GC}}^{\text{red}}$ were available for 9 systems in our sample (including the red sub-population for the Milky Way). The data points as well as the best-fit relations are shown in Figure 2 (the same fitting techniques detailed in section 3 were used here for the red and blue GCs). The relation we find has $\alpha = 8.73 \pm 0.09$ and $\beta = 3.84 \pm 0.52$ with an intrinsic scatter $\varepsilon_0 = 0.22$ making it a tighter relation than the $M_{\text{BH}} - \sigma_{\text{ph}}$ for the same sample. However, since the Milky Way probes a rather different region of parameter space and because its black hole mass is known to high accuracy compared to other systems, it could potentially introduce a bias in the estimation of the parameters. Nonetheless, we found little difference in the resulting parameters even if we removed the Milky Way. We also point out that both fitting methods gave almost the same results indicating that the parameters are well-constrained. We note that our value of $\beta$ is close to the value given by G09 for early-type galaxies ($\beta = 3.86$) and ellipticals ($\beta = 3.96$).

For blue GCs (Figure 3), we obtain $\alpha = 8.66 \pm 0.12$ and $\beta = 3.00 \pm 0.72$ without including the MW. The intrinsic scatter $\varepsilon_0 = 0.33$ is larger than the previous one obtained for either the full GC system or for the red GCs and the slope is also only marginally consistent with both estimates. Thus, it seems that SMBHs and metal-poor GCs are only weakly connected. Note that if we include the MW, we obtain a higher value for the slope $\beta = 4.07 \pm 0.89$ which is more consistent with G09 and with the metal-rich GCs but the scatter is even larger in this case.

Finally, we point out that, according to our best-fit relations for red and blue GCs, there is a preferred value of $M_{\text{BH}}$ for NGC 1399 and NGC 5128 (Figure 2 and 3) which

| Galaxy | $\sigma_{\text{GC}}^{\text{red}}$ (km s$^{-1}$) | Ref. | $M_{\text{BH}}$ ($M_\odot$) |
|--------|---------------------------------|------|-----------------|
| NGC 1407  | 243$^{+21}_{-15}$  | 1   | 1.12 $\pm$ 0.42 $\times 10^9$ |
| NGC 3923  | 200$^{+22}_{-22}$  | 2   | 5.31 $\pm$ 2.50 $\times 10^8$ |
| NGC 4494  | 92$^{+8}_{-8}$    | 3   | 2.69 $\pm$ 2.04 $\times 10^7$ |
| M33       | 42$^{+18}_{-8}$   | 4   | 1.32 $\pm$ 1.93 $\times 10^6$ |
| LMC       | 17                 | 5   | 4.11 $\pm$ 5.36 $\times 10^4$ |

Table 3. Estimated black hole mass using the measured velocity dispersion of the red GCs sub-population.

are $M_{\text{BH}} = 3.0 \times 10^8 M_\odot$ and $M_{\text{BH}} = 1.3 \times 10^9 M_\odot$ respectively.

5 PREDICTION OF $M_{\text{BH}}$ FOR FIVE GALAXIES

As we have shown, $\sigma_{\text{GC}}^{\text{red}}$ seems to be the best proxy for black hole mass for the sample we considered. Thus, we use the $M_{\text{BH}} - \sigma_{\text{GC}}^{\text{red}}$ relation to estimate the black hole mass of galaxies for which $\sigma_{\text{GC}}^{\text{red}}$ is known, namely for NGC 1407, NGC 3923, NGC 4494, M33 and the LMC (Table 3).

- M33 - We obtain $M_{\text{BH}} = 1.32 \pm 1.93 \times 10^6 M_\odot$ which is consistent with M33 having no central black hole. We remark that Gebhardt et al. (2001) have used the $M_{\text{BH}} - \sigma_{\text{ph}}$ relation ($\alpha = 8.11$ and $\beta = 3.65$) to estimate the black hole mass in M33. They found $5.6 \times 10^5 M_\odot$. Merritt et al. (2001) find $M_{\text{BH}} = 3 \times 10^5 M_\odot$ as an upper limit. They conclude that either M33 does not contain a BH or has an intermediate mass black hole or that the $M - \sigma$ relation cannot be extrapolated to such low masses. Using the observed relation between circular velocity at large radii and black hole mass, Gebhardt et al. (2001) have calculated a mass of $M_{\text{BH}} \sim 6 \times 10^6 M_\odot$ X-ray observations give $M_{\text{BH}} \sim 10 M_\odot$. Using also X-ray data and a different method, Dubus et al. (2004) find a black hole mass in the range $10^5 - 10^6 M_\odot$. Further data are needed before a final conclusion can be drawn.

- LMC - The Large Magellanic Cloud, being a satellite galaxy, is clearly different from the other systems in the sample used to derive the $M_{\text{BH}} - \sigma_{\text{GC}}$ relation. The centre is not well defined and its globular clusters are not old. However, since the kinematics of the GC system is available (Freeman 1993), we simply mention that assuming the $M_{\text{BH}} - \sigma_{\text{GC}}$ relation can be applied it predicts $M_{\text{BH}} \sim 4.1 \pm 5.4 \times 10^5 M_\odot$ which hints towards an intermediate mass black hole but is also consistent with the LMC having no central black hole.

The black hole mass estimates are summarised in Table 3.

The present paper, we have shown that the velocity dispersion of globular cluster systems projected on the line-of-sight
that is the observed radial velocities) is well-correlated with the mass of central black holes, particularly for red (metal rich) globular clusters. The slope of the correlation is similar to the one obtained by G09 but the normalisation is different, meaning that at fixed black hole mass, the velocity dispersion of the globular cluster system is smaller than the dispersion of the spheroid. We also show that the relation for red clusters has the same slope as that of G09 for early-type galaxies. Thus, it seems that the relation with red GCs to estimate the black hole mass in NGC 1407, NGC 4494, NGC 3923, M33 and the LMC.

**ACKNOWLEDGMENTS**

We wish to thank Karl Gebhardt and Julie Nantais for providing us with unpublished data, Roya Mohayaeæ, Scott Tremaine, Marta Volonteri, William and Gretchen Harris for interesting discussions and the anonymous referee for relevant comments which helped improving the paper. Support from ANR OTARIE is acknowledged.
