ABSTRACT

We investigate the ionization mechanisms for hidden broad-line region (HBLR) and non-HBLR Seyfert 2 galaxies by comparing some optical emission line ratios. We note that the [N ii] / Hα ratio of the non-HBLR Seyfert 2 galaxies is significantly higher than that of the HBLR Seyfert 2 galaxies while other line ratios, such as [O iii]/Hβ and [O i]/Hα, are similar. To probe the origin of this difference, we explore theoretical results of different ionization models, such as photoionization, starburst, and shock models. We find that none of these models can explain the high [N ii] / Hα ratio of the non-HBLR Seyfert 2 galaxies with solar abundance; the high [N ii] / Hα must be reproduced from enhanced nitrogen abundance. Since nitrogen overabundance can be achieved from the dredge-up of red supergiants in the post-main-sequence stage, we suggest that the observed nitrogen overabundance of the non-HBLR Seyfert 2 galaxies might be caused by stellar evolution, and there could be an evolutionary connection between the HBLR and non-HBLR Seyfert 2 galaxies.

Key words: galaxies: active – galaxies: nuclei – galaxies: Seyfert

1. INTRODUCTION

Seyfert galaxies are classified as radio-quiet active galactic nuclei (AGNs) and further divided into two subtypes, Seyfert 1 and Seyfert 2, according to their different optical line widths. Based on the orientation-based unification model (Antonucci & Miller 1985; Antonucci 1993), Seyfert 2 galaxies are considered to be the same objects as Seyfert 1 galaxies but viewed from a different direction. The detection of polarized broad permitted emission lines in several Seyfert 2 galaxies further supported this unification model (Tran 1995; Young et al. 1996a, 1996b; Heisler et al. 1997; Moran et al. 2000). However, previous studies showed that only about 40%–45% of Seyfert 2 galaxies have polarized hidden broad-line regions (HBLRs; Heisler et al. 1997; Gu & Huang 2002). Spectro-polarimetric studies of Seyfert 2 galaxies showed that the HBLR Seyfert 2 galaxies have higher luminosities in the [O iii], optical, radio, and mid-infrared than the non-HBLR Seyfert 2 galaxies (Gu & Huang 2002; Tran 2003). Besides, for several observational properties, such as $S_{20\text{cm}}/f_{60}$, $f_{25}/f_{60}$, and $L_{[O\text{iii}]}$, the HBLR Seyfert 2 galaxies are found to be similar to Seyfert 1 galaxies, and the non-HBLR Seyfert 2 galaxies are noted to be more like H ii/starburst galaxies (Gu & Huang 2002; Deluit 2004).

It is unclear why some but not all Seyfert 2 galaxies have detectable HBLRs. Several possibilities have been proposed. (1) From the ratios of $f_{25}/f_{60}$, Heisler et al. (1997) suggested that the detectability of the HBLRs in Seyfert 2 galaxies is related to the inclination of the torus. (2) Some evolutionary processes might be at work between the HBLR and non-HBLR Seyfert 2 galaxies (Tran 2003). (3) Zhang & Wang (2006) found that the non-HBLR Seyfert 2 galaxies and narrow-line Seyfert 1 galaxies (NLS1s) have a similar distribution of black hole masses, accretion rates, and ratios of $f_{25}/f_{60}$. They thus concluded that the non-HBLR Seyfert 2 galaxies are the counterparts of the NLS1s at edge-on orientation. (4) The non-HBLR Seyfert 2 galaxies could be mainly powered by nuclear starbursts rather than accretion onto the central black hole (Yu & Huang 2005). (5) From X-ray data, Shu et al. (2007) indicated that the nuclear activity and obscuration might play an important role in the visibility of polarized broad lines. (6) Elvis & Ho (2009) showed that the broad-line regions (BLRs) might disappear at low luminosities in advection-dominated accretion models. (7) Tran et al. (2011) suggested that some Seyfert 2 galaxies could intrinsically lack BLRs. (8) Some Seyfert 2 galaxies might be deficient in scattering material.

Emission lines have long been used to distinguish the origin of active galaxies. For example, optical emission lines of Seyfert 2 galaxies, such as [O iii], [O i], [N ii], and [S ii], are usually more stronger than those of H ii/starburst galaxies relative to the recombination lines. For Seyfert galaxies, photoionization from a power-law continuum, presumably from the central AGN, is proposed to be responsible for the ionization mechanisms and is generally successful in reproducing observed optical lines (Veilleux & Osterbrock 1987). If the non-HBLR Seyfert 2 galaxies were powered by nuclear starburst activities, one important question is how the narrow-line regions (NLRs) of the non-HBLR Seyfert 2 galaxies are ionized. However, we note that Terlevich et al. (1992) have showed that most of the line ratios of the Seyfert 2 galaxies could be reproduced by starburst models. Besides, a photoionization model with power-law continuum might fail to reproduce all observed properties in some cases. For example, observations of [O iii] suggested that the electron temperature could be up to $\sim 22,000$ K (Tadhunter et al. 1989) while the photoionization model could only yield a lower electron temperature ($\sim 11,000$ K). Therefore, some other physical processes, such as shock heating and starbursts, might also play a significant role in a photoionization-dominated model (Kraemer et al. 1998). These results suggest that we need to consider different ionization mechanisms when we investigate the origin of the ionization of Seyfert 2 galaxies.

In this paper, we investigate and compare possible ionization mechanisms of the NLRs for the HBLR and non-HBLR Seyfert 2 galaxies by considering photoionization, shock-wave heating, and starburst models. We calculate line ratios of the photoionization model with the CLOUDY program version 08.00, last described by Ferland et al. (1998). The shock models are obtained from the library calculated by Allen et al. (2008) with the Mappings iii code, and the starburst models are obtained from Kewley et al. (2001a).
2. LINE RATIOS OF HBLR AND NON-HBLR SEYFERT 2 GALAXIES

2.1. Diagnostic Diagrams

Active galaxies, such as starburst and Seyfert 2 galaxies, show narrow emission lines in their spectra. The line ratio $[\text{O} \text{iii}] \lambda 5007/\text{H} \beta \gtrsim 3$ was found to be a good criterion to separate Seyfert 2 and starburst or H II-like galaxies (Shuder & Osterbrock 1981). However, some starburst galaxies were also found to have $[\text{O} \text{iii}] \lambda 5007/\text{H} \beta \gtrsim 3$ (Osterbrock & De Robertis 1985). Other line ratios, such as $[\text{N} \text{ii}] \lambda 6583/\text{H} \alpha$, $[\text{O} \text{i}] \lambda 6300/\text{H} \alpha$, and $[\text{S} \text{ii}] \lambda \lambda 6716,6731/\text{H} \alpha$, are also needed to separate the starburst and Seyfert 2 galaxies (Baldwin et al. 1981; Veilleux & Osterbrock 1987). In Figure 1, we show the diagnostic diagram of these line ratios; the data of the HBLR and non-HBLR Seyfert 2 galaxies are collected from the literature and are listed in Table 1. The data of H II-like galaxies and LINERs are adopted from Ho et al. (1997).

Beside the well-known separation between the starburst and Seyfert 2 galaxies, we note that the distribution of non-HBLR Seyfert 2 galaxies is very different from that of HBLRs. The difference is mainly caused by the different line ratio of $[\text{N} \text{ii}] \lambda 6583/\text{H} \alpha$. Both the Kolmogorov–Smirnov test ($P = 99.7\%$) and Student’s $T$-test ($P = 99.9\%$) show that the $[\text{N} \text{ii}] \lambda 6583/\text{H} \alpha$ distribution of the HBLR and non-HBLR Seyfert 2 galaxies is significantly different. This indicates that the HBLR and non-HBLR Seyfert 2 galaxies have different physical conditions. In order to understand the physical properties of these Seyfert 2 galaxies, we compare the observed data with different ionization mechanisms in the following.

2.2. Models

Seyfert galaxies are usually considered to be photoionized by central AGNs. The ionization source is suggested to be a power-law continuum (Koski 1978). In order to compare with the observed data, we use the CLOUDY program to produce the line ratios. The CLOUDY package is designed to simulate photoionization of clouds with different incident continuum. We assume that the incident ionizing continuum is a power law with an index $p = 1.4$ and the distance from the cloud to the central continuum is set to be 100 pc. The derived ionization parameter $\Gamma$ varies from $10^{-1.5}$ to $10^{-3.5}$ (upper left to lower right for each model), and the density $n_{\text{H}}$ varies from $10^{2}$ to $10^{5} \text{ cm}^{-3}$.

Figure 2 shows the results of CLOUDY models with different nitrogen abundances. Figure 2(a) shows that the relative emission between $[\text{O} \text{iii}]$ and $[\text{O} \text{i}]$ is very different from expected. Figure 2(b) indicates that the high $[\text{N} \text{ii}] \lambda 6583/\text{H} \alpha$ ratio of the non-HBLR Seyfert 2 galaxies can be reproduced by increasing the nitrogen abundance to five times solar abundance (5 N$_{\odot}$). We note that if we simply increase all metal abundance, the $[\text{O} \text{iii}]$ emission would also increase as well and not reproduce the observed $[\text{N} \text{ii}] / [\text{O} \text{iii}]$ ratio. This result suggests that the non-HBLR Seyfert 2 galaxies might...

Another possible ionization mechanism is starbursts. A large library of starburst models has been presented by Kewley et al. (2001a). However, as shown in Figure 1, only three sources lie on the extreme starburst region. It is obvious that the [N ii] and [O iii] line emission of the non-HBLR Seyfert 2 galaxies cannot be reproduced by the starburst models. Furthermore, if the [N ii] emission is from the starburst region, high [O iii] emission would be expected. However, the average [O ii]/[O iii] ratio is $0.23 \pm 0.16$ and $0.26 \pm 0.09$ for the HBLR and non-HBLR Seyfert 2 galaxies (Gu et al. 2006), indicating that the contribution from star formation in both types of galaxies is similar. Besides, Kewley et al. (2001a) indicated that the contribution from supernovae to the starburst models is $\ll 20\%$ and can be neglected. Therefore, the starburst models would hardly explain these line ratios even including supernova contribution.

Based on these results, all the line ratios cannot be reproduced by a single model. This might not be unreasonable since NLRs could be composed of clouds with different ionization conditions. For example, the [O iii] emission could come from highly ionized regions that are powered by AGNs, while [N ii] emission may come from lower ionized regions. One possibility that could explain the observed line ratios is a composite model of an AGN continuum and starburst and/or shock. However, the [N ii]/Hα line ratios produced by these three single models with solar abundance are all much less than the observed ratios, so any combination of these three models cannot produce enough [N ii] emission for the non-HBLR Seyfert 2 galaxies. This result suggests that the high [N ii]/Hα ratios must be due to overabundance of nitrogen in the non-HBLR Seyfert 2 galaxies.

3. DISCUSSION

It is not unusual for Seyfert 2 galaxies to show enhanced nitrogen abundance. Previous studies showed that the nitrogen abundance of Seyfert 2 galaxies can reach as much as 3.5−5 times solar abundance (Storchi-Bergmann & Pastoriza 1990). Our results further show that the non-HBLR Seyfert 2 galaxies have higher nitrogen abundance than the HBLR Seyfert 2 galaxies. Comparing these results, we suggest that the high

Figure 3. Correlation between [N ii] and [S ii] emission. The results of photoionization models are also plotted in the diagram for comparison. Symbols are the same as in Figure 1. The ionization parameter $\Gamma$ varies from $10^{-1.5}$ to $10^{-3.5}$ (lower left to upper right for each model), and the density $n_{\text{H}}$ varies from $10^{2}$ to $10^{4}$ (left to right for each model).

have higher N/O relative abundance than the HBLR Seyfert 2 galaxies. However, as shown in Figure 2(c), the [S ii] emission cannot be reproduced with both $N_{\text{e}}$ and $5 N_{\text{O}}$ abundance.

To investigate the origin of the [S ii] emission, we compare the emission of [N ii] with that of [S ii] in Figure 3. There is a significant correlation between [N ii] $\lambda 6583$/Hz and [S ii] $\lambda 6716,6731$/Hz for both HBLR and non-HBLR Seyfert 2 galaxies as shown in Figure 3. This indicates that the emission of both [N ii] and [S ii] must have the same origin. We also note that the correlations might have different slopes for both kinds of galaxies; the non-HBLR Seyfert 2 galaxies seem to have a slightly steeper slope than the HBLR Seyfert 2 galaxies. Furthermore, the photoionization model has difficulty explaining the high [N ii]. This suggests that some other mechanisms might be operative for producing the observed [S ii] and [N ii] emission.

One possible excitation mechanism for the NLRs of Seyfert 2 galaxies is shock-wave heating. Allen et al. (2008) have presented a library of radiative shock models calculated using the MAPPINGS III code. The parameters in the library have broad ranges with a pre-shock density $n$ from $0.01$ to $1000$ cm$^{-3}$, a shock velocity $v$ from $100$ to $1000$ km s$^{-1}$, pre-shock magnetic fields $B$ from $10^{-10}$ to $10^{-4}$ G, and magnetic parameter $B n^{1/2}$ from $10^{-4}$ to $100$ $\mu$G cm$^{3/2}$.

The shock model with standard solar abundance can reproduce the distribution of the [O i] and [S ii] emission. However, the [N ii] emission of the non-HBLR Seyfert 2 galaxies can be reproduced only by increasing the metal content to two times solar abundance in the shock models. This result further suggests that the nitrogen abundance of the non-HBLR Seyfert 2 galaxies is higher than that of the HBLRs. However, it is noted that the shock models cannot produce enough [O iii] emission. By adding ionized pre-shock gas in the shock models, Allen et al. (2008) might be able to produce high enough [O iii] emission but would fail to produce the observed [N ii] emission. These results show that shock models are unable to reproduce these observed line ratios simultaneously.
The difference between the HBLR and non-HBLR galaxies might be caused by their stellar evolution. Based on evolutionary models of starburst activities, Matteucci & Padovani (1993) showed that the N/O relative abundance reaches a maximum value at about $3 \times 10^8$ years. The nitrogen could be dredged up from red supergiants in the post-main-sequence stage, and this would result in the nitrogen overabundance. Therefore, the super-solar nitrogen abundance of the non-HBLR Seyfert 2 galaxies may imply that the starburst activities in the non-HBLR Seyfert 2 galaxies are in the post-main-sequence stage.

The high abundance of the non-HBLR Seyfert 2 galaxies implies that there could be an evolutionary connection between the non-HBLR and the HBLR Seyfert 2 galaxies. AGNs have been suggested to be related to circumnuclear star formation. Accreted gas is transported to the central regions to fuel the AGNs; the transported gas accumulates around the nucleus and might also trigger star formation. The super-solar abundance suggests that the non-HBLR Seyfert 2 galaxies are in older stages of stellar evolution than the HBLR Seyfert 2 galaxies. This would also imply that the gas around the nucleus of the non-HBLR Seyfert 2 galaxies might have diminished, which would cause low accretion rates for the non-HBLR Seyfert 2 galaxies. This is consistent with the results found by Bian & Gu (2007), which showed that the accretion rates of non-HBLR Seyfert 2 galaxies are lower than those of HBLR Seyfert 2 galaxies. When the accretion rate is below some thresholds, the BLRs could disappear (Nicastro et al. 2003); therefore, no polarized broad lines are observed in the non-HBLR Seyfert 2 galaxies.

4. SUMMARY

We investigate the ionization mechanisms of the HBLR and non-HBLR Seyfert 2 galaxies by comparing the photoionization, shock, and starburst results with observations. A possible explanation for all observed emission might require a combination of different models; for example, the [O III] emission could come from highly ionized regions that are powered by AGNs, while [N II] emission may come from lower ionized regions powered by starbursts or shock waves. However, our results show that the non-HBLR Seyfert 2 galaxies must have higher relative N/O abundance than the HBLR Seyfert 2 galaxies. The high N/O relative abundance could originate from stellar evolution and imply an evolutionary connection between the HBLR and the non-HBLR Seyfert 2 galaxies. As an HBLR Seyfert 2 galaxy evolves, the gas around the nucleus diminishes, resulting in low accretion rates and depletion of the BLRs; this evolution might transfer HBLR Seyfert 2 galaxies to non-HBLR galaxies.

We thank the referee for constructive comments. We are also grateful to the groups and persons who provide the cloudy code and the mappings III library.
