Diffusive low optical depth particle disks truncated by planets

ABSTRACT

Two dimensional particle disks in proximity to a planet are numerically integrated to determine when a planet in a circular orbit can truncate a particle disk. Collisions are treated by giving each particle a series of velocity perturbations during the integration. We estimate the mass of a planet required to truncate a particle disk as a function of collision rate, related to the disk optical depth, and velocity perturbation size, related to the disk velocity dispersion. We find that for particle disks in the regime estimated for debris disks, a Neptune mass planet is sufficiently massive to truncate the disk. If both the velocity dispersion and the disk optical depth are low (dispersion less than approximately 0.02 in units of circular motion, and optical depth less than $10^{-5}$) then an Earth mass planet suffices. We find that the disk is smooth and axisymmetric unless the velocity perturbation is small and the planet mass is of order or greater than a Neptune mass in which case azimuthal structure is seen near prominent mean motion resonances.

1 INTRODUCTION

Recent observations made with the Spitzer Space Telescope have added to the total number of known debris and circumstellar disks (Rieke 2005; Beichman et al. 2006; Gorlova et al. 2006; Chen et al. 2006; Bryden et al. 2006). These disks have total infrared opacity, as estimated from the fraction of stellar light re-emitted in the infrared, in the range $\tau_{IR} \sim 10^{-3} - 10^{-5}$. Infrared spectra of many debris are well fit with a single black body temperature suggesting that they possess inner holes (Chen et al. 2006). Planets are suspected to be responsible for the inner clearings (e.g., Kalas et al. 2005; Quillen 2006; Chen et al. 2006).

The fraction of starlight absorbed by the dust is related to the timescale between dust particle collisions. Here we focus on collisions as they are expected to make significant modifications to the dynamics. The relation between the fraction of starlight absorbed by the dust and the collision timescale depends on the width and radius of the disk. A ring with radius $r$, width $dr$, and optical depth normal to the disk plane, $\tau_n$, has total surface area $A = 2\pi r dr \tau_n$; however at radius $r$ the starlight passes through a sphere of area $4\pi r^2$. For low opacity systems the infrared opacity is related to the disk optical depth by

$$\tau_n \approx \frac{2r}{dr} \tau_{IR}.$$  \hspace{1cm} (1)

We expect that the disk optical depth, $\tau_n$, exceeds $\tau_{IR}$ by a modest factor ($dr < r$) and that $\tau_n$ is the same order of magnitude as $\tau_{IR}$ unless the ring is very narrow. The infrared opacity measurements allow us to crudely estimate the normal disk optical depth and so collision timescale in the disk, though when possible, direct imaging in the infrared can provide better measurements (e.g., Marsh et al. 2007).

Planets have been proposed to explain the morphology of a number of systems with dusty disks (e.g., Ozernoy et al. 2006; Wilner et al. 2002; Quillen & Thorndike 2002; Wyatt 2003; Deller & Maddison 2005), however most models do not take into account collisions between particles in the disk. The collision timescale, $t_{col}$, for the smaller particles can be estimated from the optical depth, $\tau_n$, normal to the disk plane,

$$t_{col} \sim (3\tau_n n)^{-1}.$$  \hspace{1cm} (2)

Hanninen & Salo 1992 where $n$ is the mean motion at radius $r$. As emphasized by Dominik, & Decin (2003), Wyatt (2003), for most debris disks the collision timescale between particles is shorter than the Poynting-Robertson drag timescale and so collisions should be considered when interpreting the evolution and morphology of these disks. Quillen 2006 proposed that the steep inner edge of Fomalhaut’s disk might be due to the removal (by the planet) of particles scattered interior to the disk edge by collisions. While Quillen 2006 suggested that the chaotic zone near the corotation region is a likely location for disk truncation, this has yet to be tested by numerical simulations that incorporate both perturbations by a planet and collisions on a timescale consistent with that expected for debris disks. That is what we aim to do here.

For disk optical depths in the regime of debris disks, $\tau_n \lesssim 10^{-2}$, spiral density waves cannot be driven at Lindblad resonances (Quillen 2006); this regime is also discussed in the context of planetary rings by Franklin et al. 1984; Hanninen & Salo 1992; Lissauer & Espressat 1993; Espresate & Lissauer 2004). However collision induced an...
Numerical integrations were carried out in the plane, using massless particles under the gravitational influence of only the star and a massive planet with zero eccentricity, $e_p = 0$, by Espresate & Lissauer (2001). A more sophisticated simulation would allow the particle distribution to set both collision timescale and momentum perturbation are chosen independently of the particle distribution (similar to the approach by Espresate & Lissauer [2001]). A more sophisticated simulation would allow the particle distribution to set both quantities (e.g., Melita & Woolfson [1998]). However this requires additional computational effort, either by computing close approaches carefully (Charnoz et al. 2001), letting the computed collisions depend on a numerical grid (Lithwick & Chiang 2006) or integrating sufficient numbers of particles that the velocity distribution is well sampled (Melita & Woolfson 1998).

2 NUMERICAL INTEGRATIONS

Numerical integrations were carried out in the plane, using massless particles under the gravitational influence of only the star and a massive planet with zero eccentricity, $e_p = 0$, by Espresate & Lissauer (2001). A more sophisticated simulation would allow the particle distribution to set both collision timescale and momentum perturbation are chosen independently of the particle distribution (similar to the approach by Espresate & Lissauer [2001]). A more sophisticated simulation would allow the particle distribution to set both quantities (e.g., Melita & Woolfson [1998]). However this requires additional computational effort, either by computing close approaches carefully (Charnoz et al. 2001), letting the computed collisions depend on a numerical grid (Lithwick & Chiang 2006) or integrating sufficient numbers of particles that the velocity distribution is well sampled (Melita & Woolfson 1998).
and semi-major axis, $a_p = 1$, using a conventional Burlisch-Stoer numerical scheme. Initial particle mean anomalies and longitudes of perihelia were randomly chosen. In each simulation $1000$ particles were integrated for $\sim 10^5$ planetary orbital periods.

Each particle suffers collisions with a mean collision rate set by the collision timescale. The parameter we use to describe the collision rate is the number of collisions per planet orbit, $N_c$, for an individual particle; $N_c \approx P/t_{\text{col}}$, where $P$ is an planet orbital period. The parameter $N_c$ is related to the normal disk optical depth by $N_c \approx 18\tau_n$ (Hanninen & Salo 1992). Each planetary orbit the number of collisions is computed from the total number of particles in the simulation and the collision rate. The particles that receive collisions are chosen randomly from those integrated. These particles receive perturbations to their momentum at a randomly chosen time during the orbit.

If a particle suffers a collision its radial velocity is adjusted to damp the energy,

$$v_r \to \epsilon v_r,$$

(5)

where $-1 < \epsilon < 1$. Here we have set $\epsilon = 0$. Had we not restricted our simulations to zero eccentricity planets we would have required the radial velocity perturbation to depend on the mean set by the distribution of particles. The tangential velocity is given a random kick

$$v_\phi \to v_\phi + \Delta v,$$

(6)

where $\Delta v$ is chosen from a normal distribution with dispersion $\sigma_{dv}$. Because the velocity perturbation at each collision, $\Delta v$, is chosen from a normal distribution its expectation is zero. While total angular momentum should not drift rapidly, angular momentum is not conserved during the simulation. Adjustment or redistribution of angular momentum following collisions would be required to conserve angular momentum (e.g., as explicitly described by Melita & Woolfson 1998). We do not chose to do this as we continually regenerate particles that have scattered outside the region of interest. To conserve angular momentum computational time would have been wasted integrating particles that diffuse away from the planet as well as toward it. Our adopted procedure allows us to simulate a diffusive disk with minimal time spent integrating particles outside the region near the planet.

Particle initial semi-major axes were chosen to lie between $1.4$ and $1.5$ times the semi-major axis of the planet. This way the particles were allowed to diffuse from larger radius, approaching the planet. Particles are removed from the simulation if they have a semi-major axis greater than $1.6$ or less than $0.7$, have an eccentricity greater than $0.5$ or are unbound and if they move closer to the planet than $1/10$ of its Hill radius. Particles that are removed from the simulation are regenerated choosing their orbital parameters in the same way as the initial particles were chosen. This ensures that a constant number of particles is integrated at all times.

The initial particle eccentricities were drawn from a Rayleigh distribution with a mean eccentricity of $e_{\text{init}}$ that is chosen to match the velocity perturbation parameter, $\sigma_{dv}$ or

$$e_{\text{init}} = \sqrt{8} \sigma_{dv} / v_K,$$

(7)

where $v_K$ is the velocity of a particle undergoing circular motion at the radius of the planet. A particle in a nearly circular orbit with eccentricity $e$ has radial velocity component $\Delta v_r = e \sin nt$ and tangential component $\Delta v_\phi = (1 + \frac{1}{a} \cos nt)$. A distribution of particles with the same eccentricity and random mean longitudes and longitudes of periastron has radial dispersion $\langle \epsilon^2 >_r = \frac{e^2}{2}$ and $\langle \epsilon^2 >_K = \frac{e^2}{2}$. This last expression accounts for the factor of $\sqrt{8}$ in equation (7). We describe and refer to simulations in terms of either the velocity perturbation, $\sigma_{dv}$, or the mean initial particle eccentricity, $e_{\text{init}}$, as they are directly related to one another.

A steady state is reached after the disk has had time diffuse from the generation region (at a radius of $1.4-1.5$) to the particle removal region, near the planet’s orbital radius. We checked that the radial velocity dispersion distant from the planet (greater than $r \sim 1.2$) is that expected from perturbations given to the tangential velocity perturbation at each collision or $< v_\phi ^2 > \approx 4 \sigma_{dv}^2$. This is consistent with a distribution of particles with a mean eccentricity of $< e > = e_{\text{init}} = \sqrt{8} \sigma_{dv} / v_K$. Because the radial velocity component is damped at each collision the mean particle eccentricity does not significantly increase past this value except near the planet.

A density distribution is created from particle positions at the same time (planet mean anomaly) in each planetary orbit. We have added $1000$ of these from different timesteps (each at the same time in the planet’s orbit) to ensure that the density distributions are smooth and have a large dynamic range. We work in units of the planet’s semi-major axis, $a_p$, and orbital period. The mass of the planet is described in terms of its mass ratio, $\mu$, the ratio of the planet mass to that of the central star. We describe the velocity perturbation $\sigma_{dv}$ in units of the velocity of a particle in a circular orbit, $v_K$, or in terms of the associated initial particle eccentricity, $e_{\text{init}}$.

### 3 SIMULATIONS

We relate the simulation parameters to quantities that can be constrained by observations, the disk normal optical depth, $\tau_n$, and the velocity dispersion that is related to the disk thickness. We have run simulations for three different planet mass ratios, $\mu = 10^{-4}, 10^{-5}$ and $10^{-6}$, two different collision rates, $N_c = 10^{-2}$ and $10^{-3}$ collisions per particle per orbit corresponding to disk normal optical depths $\tau_n = 0.5 \times 10^{-5}$ and $0.5 \times 10^{-3}$ and four different velocity perturbation sizes. In Table 1 the velocity perturbation sizes are listed in terms of the initial mean eccentricity $e_{\text{init}}$ where $\sigma_{dv} / v_K = e_{\text{init}} / \sqrt{8}$ and are related to the disk velocity dispersion by $(u/vK)^2 \approx e_{\text{init}}^2 / 2$.

Azimuthally averaged density profiles (number density as a function of radius) after equilibrium is reached are shown in Figures 1a - 4a where each figure shows simulations with only one planet mass. A comparison of Figure 1a - 1c suggests that the radius at which the particle number density drops is related to the planet mass.

In the collisionless restricted 3 body system there is
an abrupt change in dynamics in the corotation region at a semi-major axis that we refer to as the boundary of the chaotic zone. The width of this zone has been measured numerically and predicted theoretically by predicting the semi-major axis at which the first order mean motion resonances overlap (Wisdom 1980; Murray & Holman 1997). In our figures we have with an arrow marked the chaotic zone boundary at a radius \( r_z = a_p + d_a \), with the distance between the planet and chaotic zone \( d_a = 1.5 a_p \mu^{2/7} \) (Wisdom 1980; Duncan et al. 1989) for the different simulations. We see from the figures that this boundary is approximately the location at which the radial profiles suffer a drop near the planet, as would be expected from the change in the dynamics due to overlap of mean motion resonances (Wisdom 1980; Murray & Holman 1997; Quillen & Faber 2006).

We note that the density drops before the chaotic zone boundary for the simulations with the most massive planets. The simulations with the most massive planet and the steepest profiles are also the ones that show the most structure. Figures 2a and 2b display density distributions as a function of radius and angle for simulations C2 and F1. We find for planet mass ratios equal to or below \( 10^{-5} \) little structure is seen in the profiles shown in figure 2b) and a reduction in the density profile at a radius larger than the chaotic zone boundary. This is likely to be due to particle density near the planet since the velocity dispersion is not solely a function of the distance to the chaotic zone.

We now discuss diffusive descriptions for the disk edge to better understand the parameters affecting the decrease in particle density near the planet. Since the velocity dispersion is \( v^2 \approx < v^2 > \) and \( < v^2 > \approx 4 \sigma_d^2 c \), we estimate that the diffusion coefficient (equation 3) is

\[
D \approx \frac{4 \sigma_d^2 c_{\text{col}} n}{v_{\text{K}}^2}.
\]

(8)

In units of the square of the planet semi-major axis divided by the rotation period,

\[
D \approx 4 N_c \left( \frac{\sigma_d}{v_{\text{K}}} \right)^2 = \frac{c_{\text{col}}^2 N_c}{2}.
\]

(9)

The diffusion equation for an isolated ring, Equation 3 must be modified to include the effect of the planet. When a steady state is reached (\( \frac{\partial N}{\partial r} \approx 0 \)), a simple model is
The density decrement, $\Delta$, measured from the radial position $r$ is independent of $r$ when the radius has been rescaled by a factor of $(10^{-5}/\mu)^{2/7}$ so the chaotic zone boundaries for the three simulations line up. (e.g., Quillen 2006) where the right hand side represents the rate at which particles are removed from radius $r$ because of perturbations from the planet. This term is expected to be a function of planet mass and distance to the planet but could also be a function of the particle velocity distribution or eccentricity distribution.

We assume that there is only one important scale in the problem, the distance between the planet and the chaotic zone boundary, $da_z = 1.5\mu^{2/7}$. We rewrite equation (10) with $y = da_z/\mu$ and assuming that the diffusion coefficient is independent of $r$ and $N$,

$$\frac{\partial^2 N}{\partial y^2} \approx \frac{da_z^2}{D} \frac{\partial N}{\partial t} \bigg|_{\text{planet}}.$$  

A simple form for the right hand side of equation (10) describing removal of particles by the planet would be

$$\frac{\partial N}{\partial t} \bigg|_{\text{planet}} \sim \left\{ \begin{array}{ll} \frac{Nf(y)}{t_{\text{remove}}} & \text{for } 0 < y < 1 \\ 0 & \text{for } y \geq 1 \end{array} \right.$$  

(12)

When $f(y) = 1$ the solution

$$N(y) \propto e^{yl}$$  

(13)

with inverse scale length

$$l \sim \sqrt{\frac{da_z^2}{t_{\text{remove}}D}}$$  

(14)

If $f(y) = 1 - y$, then $N(y)$ is an Airy function and if $f(y) = \exp(-y)$ (as might be expected from lifetime measurements in collisionless integrations; David et al. 2003) the solution is a modified Bessel function. These solutions also behave in an exponential manner with an inverse scale length that is of the same order of magnitude as $l$. Figures 4a - 4c show that the density profiles do approach an exponential form near the planet where the density gradient is steepest. In parameters related to our simulations we expect the inverse scale length

$$l \sim 2t_{\text{remove}}^{1/2} \mu^{-2/7} N_c^{-1/2} \epsilon_{\text{init}}^{-1}.$$  

(15)

From the simulations we measure the density near the planet compared to that away from the disk edge or specifically the log of this ratio

$$\Delta \equiv \log_{10} \left( \frac{N(y=0)}{N(y \gtrsim 1)} \right).$$  

(16)

Equations (13) and (16) suggest that $\Delta$ depends on parameters describing our simulations, such as the planet mass ratio, collision rate and velocity perturbation size, however the above approximations and assumptions may be too simplistic to give an accurate prediction for the inverse scale length $l$. Furthermore $l$ contains the unknown timescale, $t_{\text{remove}}$.

The density decrement, $\Delta$, measured from the radial profiles, is plotted in Figures 5a and 5b. As predicted by equation (15) our measured density decrement is consistent with a power law function of the simulation parameters. Also as we expected $\Delta$ increases with increasing planet mass ra-
It is expected that the particle lifetime depends on the eccentricity, with shorter lifetimes or removal timescales at higher particle eccentricities. Perhaps the particle lifetime depends on the collision rate because particles tend to diffuse to higher eccentricities. Perhaps the particle lifetime depends on the collision rate because particles tend to diffuse to higher eccentricities. Perhaps the particle lifetime depends on the collision rate because particles tend to diffuse to higher eccentricities. Perhaps the particle lifetime depends on the collision rate because particles tend to diffuse to higher eccentricities. Perhaps the particle lifetime depends on the collision rate because particles tend to diffuse to higher eccentricities.

\[ \log_{10} \Delta \approx 0.12 + 0.23 \log_{10} \left( \frac{\mu}{10^{-6}} \right) - 0.1 \log_{10} \left( \frac{N_c}{10^{-2}} \right) - 0.45 \log_{10} \left( \frac{\epsilon_{\text{init}}}{0.01} \right) \]  

This function implies that the inverse scale length

\[ l \approx 3.0 \left( \frac{\mu}{10^{-6}} \right)^{0.23} \left( \frac{N_c}{10^{-2}} \right)^{-0.1} \left( \frac{\epsilon_{\text{init}}}{0.01} \right)^{-0.45}. \]  

A comparison between the measured scale length above (equation 18) and the predicted by equation 15 reveals some inconsistencies. Equation 15 implies that the length scale should be proportional to \( N^{-1/2} \) rather than \( N^{-0.1} \) as we find above. The above function measured \( l \) combined with equation 15 would imply that

\[ t_{\text{remove}} \approx 145 \left( \frac{\mu}{10^{-6}} \right)^{0.11} \left( \frac{N_c}{10^{-2}} \right)^{-0.8} \left( \frac{\epsilon_{\text{init}}}{0.01} \right)^{-1.1}. \]  

in orbital periods. It is not clear why the removal timescale would increase with planet mass. Had we used a larger scale for the distance to the chaotic zone boundary in equations 12 and 13 then the form of \( t_{\text{remove}} \) would have changed. It is expected that \( t_{\text{remove}} \) depends on the velocity perturbation size as we do expect the particle lifetime near the planet to depend on particle eccentricity, with shorter lifetimes or removal timescales at higher particle eccentricities. Perhaps the particle lifetime depends on the collision rate because particles tend to diffuse to higher and higher eccentricity between collisions. Our measured \( l \) is not as strong a function of \( N_c \) as predicted by equation 15. A better theoretical model for both particle lifetime and diffusion is required to better match the measured exponents of equation 15.

### 3.2 Disk truncation

The shallowest profiles displayed in Figures 1a - 1b represent particle disks that have sufficiently high collision rates and velocity dispersions that a planet cannot efficiently truncate the disk. It is interesting to apply our measured density decrement to estimate the minimum planet mass that can truncate a disk. We set a limit of \( \log_{10} \Delta = 0.12 \) (corresponding to a density drop of 20) from the shallowest simulations and solve equation 14 to find the mass ratio of a planet that cannot effectively truncate at disk of a particular collision rate and velocity dispersion. To truncate a low optical depth particle disk a planet must have mass ratio greater than

\[ \log_{10} \mu \gtrsim -6 + 0.43 \log_{10} \left( \frac{N_c}{10^{-2}} \right) + 1.95 \log_{10} \left( \frac{\epsilon_{\text{init}}}{0.01} \right) \]  

or in quantities more directly related to observations

\[ \log_{10} \mu \gtrsim -6 + 0.43 \log_{10} \left( \frac{\tau_\nu}{5 \times 10^{-3}} \right) + 1.95 \log_{10} \left( \frac{n}{u/v_K} \right) \]  

The function (equation 20) is plotted in figure 6 for collision rates \( N_c = 10^{-2} \) and \( 10^{-3} \) collisions per orbit corresponding to disk optical depths \( \tau_\nu = 0.5 \times 10^{-3} \) and \( 0.5 \times 10^{-4} \). Instead of plotting this minimum mass ratio as a function of \( \epsilon_{\text{init}} \) we plot as a function of velocity dispersion using \( \epsilon_{\text{init}} \sim (u/v_K)^2 \). On this plot we also show a limit corresponding to the eccentricity of a particle that would allow a particle to cross from the chaos zone boundary to the planet’s semi-major axis, or the limit \( (u/v_K) \sim 1.5 \mu^{2/7} \) we refer to this limit on the plot as \( \mu_c \). It is interesting to compare our mass limit for disk truncation to that expected for a accretion disk. A gaps opens in a viscous accretion disk when the torque driven by spiral density waves excited by a planet exceeds viscous inflow or

\[ \mu \gtrsim 40 Re^{-1} \]  

\[ (\text{Lin & Papaloizou } 1979, \text{ Bryden et al } 1999, \text{ Ward } 1997). \]

Here the inverse of the Reynolds’s number, \( Re^{-1} = \alpha(u/v_K)^2 \). We have plotted this function on Figure 5 for \( \alpha = 0.001 \). A particle disk has effective viscosity set by the diffusion coefficient of equation 3 (e.g., Murray & Dermott 1999), hence if our particle disks behaved similar to an accretion disk then this line (shown as a thin dotted line in figure 6) would like approximately on top of the dotted line for \( N_c = 10^{-2} \) with \( \alpha \sim N_c/6 \). It is interesting that the disk truncation criterion scales with velocity dispersion in the same way as the accretion disk; both require that the long timescale between collisions allows particle eccentricities to grow near the planet.

Figure 6 illustrates that for particle disks in the regime expected for debris disks, a Neptune mass planet is sufficient to truncate the disk, and if the velocity dis-
4 DISCUSSION

Here we have not considered models with dust produced in resonance (e.g., Quillen & Thorndike 2002; Wyatt 2004) but only allowed particles to diffuse inward toward resonances. In resonance, certain angles with respect to the planet have longer removal timescales than others. Effectively $\frac{d\rho}{dt}\big|_{\text{planet}}$ depends on the orbital elements of the particle distribution and the diffusion equation should be expanded to depend not on radius but all the orbital elements. Individual resonances may play an important role setting the velocity dispersion disks near larger planets causing increased diffusion near the disk edge (e.g., Quillen 2006; Quillen & Faber 2006). We expect additional complexity and structure if particles are produced trapped in resonance or if the system is not in a steady state. The simulations were run an average of $10^5$ orbits which is long compared to the age of some large debris disks. Our integration times are long because we allowed particles to diffuse toward the planet from a moderately distant location and we ran each simulation sufficiently long to achieve a steady state. Additional phenomena may be discovered in evolving systems.

The simulations were carried out with a collision rate and associated collision induced velocity perturbation independent of position, however particles near the planet should have suffered fewer collisions because of the steep drop in density. Particles in the disk edge should have also suffered larger velocity perturbations as the velocity dispersion increases nearing the planet. The velocity dispersion increase (spanning a factor of a few for the largest planet) is not as significant as the density decrease nearing the planet (spanning orders of magnitude for the largest planet simulations). A more accurate simulation probably would have a steeper disk edge due to the decrease in collision rate near the planet and would have required longer to achieve equilibrium as a consequence.

Here we have adopted a diffusive approach toward simulating particle disks and neglected the role of the particle size distribution. If collisions are destructive then diffusion caused by collisions can still take place. However each diffusive step involves a destructive collision producing smaller bodies and these in turn have a shorter collision timescale. We imagine an effective diffusion coefficient that depends not only on local particle density but on the size distribution with the larger particles effectively having longer collisions times and smaller diffusion coefficients. The different sized particles also may have different velocity dispersions. In this case we would expect that the larger bodies would have smaller diffusion coefficients as the large bodies would have lower velocity dispersions. It is tempting though premature to predict that the different size particles would exhibit different disk morphologies as a consequence of their different collisional timescales and velocity dispersions.

It is interesting to compare our simulations to imaging studies of debris disks. Our lower mass limit (equation 21 see circle in Figure 6) is near but a few times lower than the previous limit set by Quillen (2006) for Fomalhaut. As noted by Quillen & Faber (2006), the dynamics of low free eccentricity particles near an eccentric planet is similar to low eccentricity particles near a planet in a circular orbit, so we can extend equation 21 to low eccentricity planets. Observations of Fomalhaut’s disk have not revealed any lumps or asymmetries in the disk, other than its eccentricity (Kalas et al. 2005), consequently the planet mass must not be high ($\mu \lesssim 10^{-4}$). Otherwise Fomalhaut’s disk would look like the disk displayed in Figure 25. Consequently we also confirm, in a different way, the upper limit for the planet mass proposed by Quillen (2006). In contrast, Epsilon Eridani’s disk does show clumpy structure (Poulton et al. 2006). If particles are produced outside resonance (as explored here) then we would infer that a moderate mass planet and low dispersion disk might account for the morphology.

5 SUMMARY

We have simulated the effect of collisions on a particle disk by introducing velocity perturbations into numerical integrations of particles under the influence of gravity from a star and a single planet. We find that the planet’s chaotic zone boundary is an approximate location for the disk edge for disks that have optical depths in the range of observed debris disks. We find that density profiles do depend on the collision timescale but are more strongly dependent on the velocity perturbation size or velocity dispersion in the disk. The simulated disk morphology is axisymmetric and smooth unless the planet mass ratio $\geq 10^{-5}$ and the velocity perturbation size $\lesssim 0.02$. For higher mass ratio planets and lower velocity perturbation simulations structure is seen in the vicinity of strong mean motion resonances at locations where particles are more quickly removed from the simulation due to interactions with the planet.

From the simulations we have measured a density decrement describing the log of the density ratio of that close to the planet and that past the disk edge. The density decrement depends on powers of the planet mass ratio, collision timescale and velocity perturbation size. With a diffusion approximation this decrement represents a scale length that might in future be predicted with better understanding of particle dynamics near the planet.

We have used our numerically measured density decrement to predict the mass of a planet required to truncate a particle disk (equation 21). The minimum planet mass required depends on the square of the disk velocity dispersion, similar to gap opening in an accretion disk. However we find that a lower mass planet can truncate a low optical depth disk than an accretion disk with an equivalent viscosity. The minimum planet mass also depends on the collision rate. As the collision rate is related to the disk optical depth and the velocity dispersion related to the disk thickness, equation 21 can be used to estimate the mass of an unseen planet from observations of debris disks.

Support for this work was in part provided by National Science Foundation grant AST-0406823, and the National Aeronautics and Space Administration under Grant No. NNG04GM12G issued through the Origins of Solar Systems Program, and HST-AR-10972 to the Space Telescope Science Institute.
Figure 5a. The log of the density decrement, $\Delta$, (related to the ratio of the density past the chaotic zone to that near the planet, see equation 16) versus the log of the velocity perturbation size. Only the simulations with $N_c = 10^{-2}$ collisions per orbit are plotted. Squares, circles and points represent simulations with planet mass ratio $\mu = 10^{-4}, 10^{-5}$ and $10^{-6}$, respectively. Also plotted is a linear function described by equation 17.

Figure 5b. Same as Figure 5a except for $N_c = 10^{-3}$.

Particle disks near planets

Figure 6. Disks can be truncated by planets with a mass ratio that lies above the lines drawn. The x-axis is the disk velocity dispersion. The solid and dashed line refer to particle disks with a limit set by equation 17 for $N_c = 10^{-2}$ and $10^{-3}$ collisions per particle per orbit, respectively. The thin dotted line is the gap opening criteria expected for an $\alpha$ accretion disk with $\alpha = 0.001$. The dot dashed line is a limit set by requiring that the disk thickness be lower than chaotic zone width. A circle has been placed at the estimated planet mass lower limit for a planet inside Fomalhaut’s disk edge using $N_c = 3 \times 10^{-2}$ expected from the normal optical depth, $\tau_n = 1.6 \times 10^{-3}$ (Marsh et al. 2005) and velocity dispersion estimated from the disk edge slope $u/v_K \sim 0.013$ (Quillen 2006).
Table 1. List of Simulations

| Name | $\mu$ | $N_c$ | $\epsilon_{\text{init}}$ |
|------|------|------|------------------|
| C1   | $10^{-4}$ | $10^{-2}$ | 0.02 |
| C2   | $10^{-5}$ | $10^{-2}$ | 0.02 |
| C3   | $10^{-6}$ | $10^{-2}$ | 0.02 |
| D1   | $10^{-4}$ | $10^{-3}$ | 0.02 |
| D2   | $10^{-5}$ | $10^{-3}$ | 0.02 |
| D3   | $10^{-6}$ | $10^{-3}$ | 0.02 |
| E1   | $10^{-4}$ | $10^{-3}$ | 0.04 |
| E2   | $10^{-5}$ | $10^{-3}$ | 0.04 |
| E3   | $10^{-6}$ | $10^{-3}$ | 0.04 |
| F1   | $10^{-4}$ | $10^{-3}$ | 0.01 |
| F2   | $10^{-5}$ | $10^{-3}$ | 0.01 |
| F3   | $10^{-6}$ | $10^{-3}$ | 0.01 |
| M1   | $10^{-4}$ | $10^{-2}$ | 0.04 |
| M2   | $10^{-5}$ | $10^{-2}$ | 0.04 |
| M3   | $10^{-6}$ | $10^{-2}$ | 0.04 |
| N1   | $10^{-4}$ | $10^{-2}$ | 0.01 |
| N2   | $10^{-5}$ | $10^{-2}$ | 0.01 |
| N3   | $10^{-6}$ | $10^{-2}$ | 0.01 |
| L1   | $10^{-4}$ | $10^{-2}$ | 0.08 |

The parameters describing the discussed simulations are as follows: The planet mass ratio is $\mu$, whereas $N_c$ is the average number of collisions suffered by each particle per planet orbit. The dispersion of the azimuthal velocity kick given each collision, $\sigma_{dv}/v_K = \epsilon_{\text{init}}/\sqrt{8}$ in units of the velocity of a particle in a circular orbit. The planet was in a circular orbit. During each collision event the radial velocity component is set to zero ($\epsilon = 0$). Particles were removed from the simulation if semi-major axis $a > 1.5$ or $a < 0.7$, eccentricity $e > 0.5$ or the particle passed within 0.1 Hill radii of the planet. Particles were generated and regenerated when removed with a semi-major between 1.4 and 1.5 and a mean eccentricity of $\epsilon_{\text{init}}$. Simulations were run $10^5$ planetary orbits excepting the F series that were run twice as long and the L1 simulation that was run half as long. These times are long because we allowed particles to diffuse toward the planet from a moderately distant location and we ran each simulation sufficiently long to achieve a steady state.
\[ \Delta \]

\[ \log_{10}(e_{\text{init}}) \]

- \( N_c = 10^{-2} \)
- \( \mu = 10^{-4} \)
- \( \mu = 10^{-5} \)
- \( \mu = 10^{-6} \)
$N_c = 10^{-3}$

$\mu = 10^{-4}$

$\mu = 10^{-5}$

$\mu = 10^{-6}$

$\Delta \log_{10}(e_{\text{init}})$
