A single-wall carbon nanotube possesses two different types of plasmons specified by the wavenumbers in the azimuthal and axial directions. The azimuthal plasmon that is caused by interband transitions has been studied, while the effect of charge doping is unknown. In this paper, we show that when nanotubes are heavily doped, intraband transitions cause the azimuthal plasmons to appear as a plasmon resonance in the near-infrared region of the absorption spectra, which is absent for light doping due to the screening effect. The axial plasmons that are inherent in the cylindrical waveguide structures of nanotubes, account for the absorption peak of the metallic nanotube observed in the terahertz region. The excitation of axial (azimuthal) plasmons requires a linearly polarized light parallel (perpendicular) to the tube’s axis.

A carbon nanotube (CNT) has a notable optical property. Namely, a CNT exhibits the absorption peaks of light with linear polarization parallel to the tube’s axis, but not for the linear polarization perpendicular to it. This optical anisotropy of a CNT is essential for characterizing a sample using Raman spectroscopy and for realizing polarized optical devices. In this paper we show that when a CNT is heavily doped, many of the absorption peaks of parallel polarized light disappear due to the Pauli exclusion principle, and this causes an absorption peak of a perpendicularly polarized light to appear in the near-infrared region. This peak is a plasmon resonance that corresponds to the surface plasmon of graphene with the wavelength on the order of nanometer.

The light polarization dependence of an undoped CNT is explained in terms of the optical selection rule and screening effect. The selection rule states that a parallel (perpendicularly) polarized light induces direct (indirect) interband transitions, see Fig. 1(a). Although indirect transition of perpendicularly polarized light is allowed by the selection rule, it is suppressed by the screening effect by a plasma mode whose frequency \( \omega_p \) is much larger than that of the excitation of an indirect transition \( \omega \) (i.e., \( \omega_p \gg \omega \)). Namely, the external electric field \( E_{\perp}^{\text{ext}} \) is screened to give a small total electric field \( E_{\perp} \):

\[
E_{\perp}(\omega) = \frac{E_{\perp}^{\text{ext}}(\omega)}{1 - (\omega_p/\omega)^2}.
\]

By assuming that \( \omega_p \) of is approximately 5 eV for \( \pi \)-plasmon in an undoped CNT, \( E_{\perp}(\omega) \) is strongly suppressed and there is almost no absorption of near-infrared light.

The heavy doping into a CNT changes the situation: doping can activate intraband transitions between two energy sub-bands (with different orbital angular momentums around the tubule axis) by a weak perturbation at low energy (see Fig. 1(b)). We find that the azimuthal motion of the electrons due to these intraband transitions causes a plasma mode to appear in a heavily doped CNT. This plasma mode originates from the surface plasmons in graphene studied in Ref. 5–8. The angular frequency
of the surface plasmons in graphene is given by
\[ \omega_{n}^{sp} = \sqrt{\frac{\sigma_{\theta}|k|}{2\epsilon \tau}} - \frac{i}{2\tau}, \]

where \( \epsilon \) is the permittivity of the surrounding material, \( \tau \) is the relaxation time, \( \sigma \) is the static conductivity, and \( k \) is a two-dimensional wavevector. Considering a CNT instead of graphene, we see that there are two distinct plasmon modes, depending on the orientations of the wavevector \( k \): one mode with \( k \) in the azimuthal direction of a cylinder is called azimuthal plasmon mode, and the other with \( k \) parallel to the axial direction is an axial plasmon mode (see the top panels of Fig. 2). In the cylindrical coordinates \((r, \theta, z)\), they have the form of the plane waves \( e^{i(n\theta - \omega t)} \) and \( e^{i(kz - \omega t)} \), respectively. The azimuthal mode shown in Fig. 2(a) has only three components of the electromagnetic (EM) fields \((E_r, E_\theta, B_z)\). The unique nonzero magnetic field \( B_z \) is perpendicular to the azimuthal direction. Similarly, the axial mode shown in Fig. 2(b) has a unique nonzero magnetic field \( B_\theta \) that is perpendicular to the axial direction. These two modes are transverse magnetic (TM) modes.

The theoretical results presented in this paper were obtained analytically by solving Maxwell equations with Ohm's law, i.e. \( \mathbf{j}_\theta = \sigma_\theta(\omega)\mathbf{E}_\theta \) for the azimuthal mode, and \( \mathbf{j}_z = \sigma_z(\omega)\mathbf{E}_z \) for the axial mode. Let us mention here that the Drude model is used to specify the dynamical conductivity \( \sigma_{\theta,z}(\omega) \) as \( \sigma_{\theta,z}(\omega) = \sigma_{\theta,z}/(1 - i\omega \tau_{\theta,z}) \), where the frequency dependence is controlled by the electronic relaxation times \( \tau_{\theta,z} \), and \( \sigma_{\theta,z}(\omega) \) reduces to the static conductivities \( \sigma_{\theta,z} \) in the zero-frequency limit. The application of Drude model to a heavily doped CNT is partly justified by the polarization function.\(^{28}\)

We now describe properties of azimuthal plasmons shown in Fig. 2(a). The calculated angular frequencies are
\[ \omega_{n}^{TM} = \sqrt{\frac{\sigma_{\theta}|n|}{2\epsilon \tau r_0}} - \frac{i}{2\tau}, \]

where \( n/r_0 \) is the wavenumber (\( n \) is a nonzero integer and \( r_0 \) is the radius of the CNT). Here, for the sake of clarity, the same materials with the permittivity \( \epsilon \) are assumed to occupy the inner and outer spaces of the CNT. When different materials occupy the inner and outer spaces of the CNT, Eq. 3 can be generalized by replacing \( \epsilon \) with \( (\epsilon_{out} + \epsilon_{in})/2 \), where \( \epsilon_{out} \) (\( \epsilon_{in} \)) is the permittivity of the outer (inner) space. We note that Eq. 3 is identical to Eq. 2, if \( n/r_0 \) is replaced with \( |k| \).

Despite the similarity between the dispersion relations of a CNT and graphene, their EM fields exhibit different asymptotic behavior. Namely, the amplitude of the azimuthal TM mode in a CNT behaves as \( \propto 1/\sqrt{\tau} \) (extended) and this mode is not a localized surface plasmon, while the surface plasmon of graphene is exponentially localized in the direction normal to the layer.\(^{43}\)

The configuration of the electric field near a CNT is illustrated in Fig. 2(a,middle). We choose the fundamental mode with \( n = 1 \) for the plot, because it is the principal state excited by a perpendicular polarization light.\(^{29}\)

Figure 2(a,middle) shows that an electric dipole forms in the inner space of a CNT, which can screen an external electric field with perpendicular polarization. Indeed, the amplitude of the TM mode in the presence of an external electric field, \( E_{\theta,n}(r) e^{i(n\theta - \omega t)} \), is given by
\[ E_{\theta,n}^{TM}(r_0) = -\frac{E_{\theta,n}^{ext}(r_0)}{1 - (\omega/\omega_{n}^{TM})^2}. \]

Thus, the induced and external fields have a phase difference of \( \pi \) at low frequencies (\( \omega \ll \omega_{n}^{TM} \)), and the total electric field (that the electrons in a CNT actually ex-
plasmon excitation by near-infrared light requires a heavily doped CNT in which more than two energy sub-bands cross the Fermi energy, as shown in Fig. 2(a,bottom). Because a charge-density fluctuation that causes the plasmon excitation requires (almost) forward scatterings that is, an intraband (vertical) transition between the electronic states with similar velocities, the Fermi energy should be located (at least) at higher than the bottom of the first sub-band. Such heavily doped CNTs are already available and absorption spectra have been obtained for them. The authors of Refs. 18 and 19 observed an unidentified absorption peak at approximately 1 eV. We attribute it to the azimuthal TM mode, because Eq. 3 satisfactorily reproduces the peak position, \( \hbar \omega_{n=0}^{TM} = 1.027 \text{ eV} \), when we use the values reported in Ref. 19 (\( \tau_0 = 10 \text{ fs} \), \( \epsilon = 2 \epsilon_0 \)), and \( 2r_0 = 1.4 \text{ nm} \)) with a realistic assumption \( \sigma_B = 4G_0 \), where \( G_0 \) is the conductance quantum. The factor 4 accounts for two azimuthal channels in each valley. The absorption spectrum is obtained by multiplying the total field with the dynamical conductivity as

\[
P(\omega) = 2\text{Re} \left\{ \frac{\sigma_B(\omega)}{1 - (\omega_{n=0}^{TM}/\omega)^2} \right\} |E_{\theta,n=1}^{ext}(r_0)|^2.
\]

We plot \( P(\omega) \) in Fig. 3. The calculated peak structure is consistent with the observation.

The azimuthal plasmon has an oscillating magnetic field that is parallel to the tube’s axis, \( B_z \), as shown in the inset of Fig. 2(a,middle). Since \( B_z \) is a periodic function of \( \theta \) (\( B_z \propto e^{im\theta} \)), the total magnetic flux inside the cylinder vanishes at any moment in time. As a result, the Aharonov-Bohm effect does not appear and there is no notable change in the electric band structure of a CNT due to the azimuthal plasmons.

Next, we examine the axial plasmon shown in Fig. 2(b). The axial TM mode oscillates with an angular frequency,

\[
\omega_k^{TM} = |k| \sqrt{\frac{\sigma_z r_0}{\epsilon \tau_z}} \ln \left( \frac{2e^{-\gamma}}{|k|r_0} \right) - \frac{i}{2\tau_z}.
\]

The dispersion is basically linear in \( |k| \) (apart from the small \( k^2 \) dependence of the logarithm) and the waves are localized, which contrasts with the properties of the azimuthal TM mode. The existence of this massless propagating mode can be understood by regarding a metallic CNT as the small waveguide. The group velocity can exceed the electron Fermi velocity for a metallic CNT with \( 2r_0 = 1.4 \text{ nm} \), \( \tau_z = 0.1 \text{ ps} \), and \( \sigma_z = 4G_0 \). The frequencies appear in the terahertz (THz) region. In Fig. 4 we show calculated THz absorption spectra that take account of the screening effect in the axial direction. The peak structure is consistent with several experiments. Some microscopic processes in a metallic CNT that contribute to the axial current of the TM mode are shown in Fig. 2(b,bottom).

![FIG. 4: Calculated THz absorption spectra for different \( \tau_z \) values as a function of angular frequency. The solid and dashed curves are for \( \tau_z = 0.1 \) and 1 ps, respectively. Here, \( \omega_k^{TM} \) is calculated from Eq. 4 by setting \( \sigma_z = 4G_0 \), \( 2r_0 = 1.4 \text{ nm} \), and \( \epsilon = \epsilon_0 \). We assume a single mode with \( k = \pi/L \) where \( L = 1 \mu m \) is the typical length of a CNT.](Image)
is similar to that of the prominent peaks of the direct transitions that appear in the near-infrared region.

In summary, we have theoretically shown that a heavily doped CNT absorbs a perpendicularly polarized light in the near-infrared region, in contrast to an undoped CNT where such an absorption is prohibited by the screening effect caused by a high-frequency plasmon. The change in the optical property is because a heavily doped CNT can support a low-frequency plasmon (azimuthal TM mode). On the other hand, when a parallel polarization light is used to excite a metallic CNT, the plasmon resonance of an axial TM mode propagating along the tube appears in the absorption spectrum in the terahertz region. These two plasmon modes correspond to the surface plasmon of graphene rolled up into a cylinder. Particularly, the azimuthal TM modes in ordinary CNTs with a diameter of close to 1 nanometer have an advantage over graphene in terms of wavelength down-conversion from visible light to nanoscale plasmons.
