Rigorous treatment of barycentric stellar motion

Perspective and light-time effects in astrometric and radial velocity data

ABSTRACT

\textbf{Context.} High-precision astrometric and radial-velocity observations require accurate modelling of stellar motions in order to extrapolate measurements over long time intervals, and to detect deviations from uniform motion caused, for example, by unseen companions.

\textbf{Aims.} We aim to explore the simplest possible kinematic model of stellar motions, namely that of uniform rectilinear motion relative to the solar system barycentre, in terms of observable quantities including error propagation.

\textbf{Methods.} The apparent path equation for uniform rectilinear motion is solved analytically in a classical (special-relativistic) framework, leading to rigorous expressions that relate the (apparent) astrometric parameters and radial velocity to the (true) kinematic parameters of the star in the barycentric reference system.

\textbf{Results.} We present rigorous and explicit formulae for the transformation of stellar positions, parallaxes, proper motions, and radial velocities from one epoch to another, assuming uniform rectilinear motion and taking light-time effects into account. The Jacobian matrix of the transformation is also given, allowing accurate and reversible propagation of errors over arbitrary time intervals. The light-time effects are generally very small, but exceed 0.1 mas or 0.1 m s\textsuperscript{-1} over 100 yr for at least 33 stars in the Hipparcos catalogue. For high-velocity stars within a few tens of pc from the Sun, light-time effects are generally more important than the effects of the curvature of their orbits in the Galactic potential.

\textbf{Key words.} methods: data analysis – technique: radial velocity – astrometry – parallaxes – proper motions – reference systems

1. Introduction

The pioneering Hipparcos mission necessitated many refinements in the analysis of astrometric observations. Effects that were previously ignored when constructing stellar catalogues, such as gravitational light deflection by bodies in the solar system and relativistic stellar aberration, had to be systematically taken into account in order to reach the milli-arcsecond (mas) accuracy made possible by observations from space. The Gaia mission, aiming at positional accuracies at the 10 micro-arcsecond (\mu as) level (de Bruijne 2012), requires further sophistication of data modelling to account for the subtle physical effects that come into play at this accuracy. A practical model for the relativistic reduction of astrometric observations, accurate to 1 \mu as, was formulated by Klioner (2003) and is the basis for the astrometric processing of the Gaia data (Lindegren et al 2012).

A basic assumption in these models is that stars move with constant velocity (speed and direction) relative to the solar system barycentre (SSB). For binaries and other non-single systems, including exoplanetary systems, their centres of mass are instead assumed to move with uniform velocity. The assumption, referred to here as the uniform rectilinear model, is fundamental in several respects. First of all, it allows us to describe the motion of any star, or the centre of mass of a multi-body system, compactly in terms of a handful of easily catalogued parameters. Secondly, it allows us to extrapolate their motions forwards and backwards in time in order to serve as comparison points for observations at arbitrary epochs. Thirdly, it provides a reference model, or null hypothesis, for the detection of non-linear motions caused for example by planetary companions. Indeed, the uniform rectilinear model is used as a reference in all modern observational analysis of stellar motions, including non-astrometric techniques such as high-precision Doppler monitoring (e.g. Choi et al 2013). In the analysis of pulsar timings, the curvature of Galactic stellar orbits is taken into account (Edwards et al 2006), but then only as a known correction to the uniform motion.

In this paper, we consider the application of the uniform rectilinear model to the problem of propagating the astrometric parameters from one epoch to another, which is a very common task in the practical use of such data. Various aspects of this problem have been extensively discussed by several authors (see Sect, but we provide for the first time a rigorous analytical solution including the propagation of uncertainties, as given by the covariance matrix of the astrometric parameters. Physical limitations of the uniform rectilinear model are discussed in Appendix.

It has long been recognized that the accurate propagation of stellar positions needs to take radial motions as well as the tangential (proper) motions into account. Thus radial velocity is inextricably connected with astrometric data and is sometimes regarded as the “sixth astrometric parameter”, complementing the standard five (for position, parallax, and proper motion) in...
defining stellar coordinates in six-dimensional phase space. In
the present paper we adopt this view even though the radial mo-
tion is usually determined by the spectroscopic method.

The astrometric parameters of a star are derived from ob-
servations using established formulae, as detailed by Klioner
(2003), to correct for local effects such as gravitational deflec-
tion and the position and motion of the observer. Similarly, spec-
troscopic Doppler measurements need to be corrected for local
and astrophysical effects as described by Lindegren & Dravins
(2003). Effectively, the result is a set of parameters describing
the observed phenomena as they would appear for a fictitious
observer located at the SSB in the absence of the gravitational
fields of all solar system bodies. The subsequent analysis of
the observations can then entirely be made in a classical (or special
relativistic) framework.

The exact relation between the uniform rectilinear model and
the astrometric parameters (including radial velocity) is simple
in principle but rather more complicated in practice, primarily
owing to the vastly different uncertainties in the radial and
tangential components of stellar coordinates. While stellar dis-
tances are seldom known to a relative precision better than 10−7,
their angular coordinates may be determined at least six orders
of magnitude more accurately. This has two important conse-
quences. First, that astrometric observations cannot easily be
modelled directly in terms of the rectangular coordinates of stel-
lar positions and velocities. The astrometric parameters, using
spherical coordinates and parallax, were introduced to overcome
this difficulty. Secondly, because the light-travel time from the
star to the observer is generally not very well known, it is cus-
tomary, and in practice necessary, to define the astrometric pa-
tameters as apparent quantities by effectively ignoring the light-
time effects. The resulting relation between the physical model
and observed quantities therefore includes both the classical ge-
ometric effects and those due to the finite speed of light.

After a brief historical review we discuss the general effects
of the light-travel time in Section 3. Section 4 presents some pre-
requisite material. Section 5 contains an analytical treatment of
the epoch transformation. Results and conclusions are summa-
rized in Sects. 6 and 7.

2. Previous work

As described by Schlesinger (1917), a star’s movement through
space causes secular changes not only in the position, but also
in its proper motion, parallax, and radial velocity as observed
from the Sun (or the SSB). These are purely geometric effects
due to the changing distance and angle between the line of sight
and the direction of motion. Schlesinger proposed that the result-
ing quadratic term in angular position, known as the secular (or
tangential) component of stellar coordinates. While stellar dis-
tances in principle but rather more complicated in practice, primar-
ily owing to the vastly different uncertainties in the radial and
tangential components of stellar coordinates. While stellar dis-
tances are seldom known to a relative precision better than 10−7,
their angular coordinates may be determined at least six orders
of magnitude more accurately. This has two important conse-
quences. First, that astrometric observations cannot easily be
modelled directly in terms of the rectangular coordinates of stel-
lar positions and velocities. The astrometric parameters, using
spherical coordinates and parallax, were introduced to overcome
this difficulty. Secondly, because the light-travel time from the
star to the observer is generally not very well known, it is cus-
tomary, and in practice necessary, to define the astrometric pa-
tameters as apparent quantities by effectively ignoring the light-
time effects. The resulting relation between the physical model
and observed quantities therefore includes both the classical ge-
ometric effects and those due to the finite speed of light.

After a brief historical review we discuss the general effects
of the light-travel time in Section 3. Section 4 presents some pre-
requisite material. Section 5 contains an analytical treatment of
the epoch transformation. Results and conclusions are summa-
rized in Sects. 6 and 7.

3. Light-time effects for the uniform motion

3.1. The uniform rectilinear model

According to the uniform rectilinear model, the barycentric vec-
tor of the star at the arbitrary epoch \( T \) is given by

\[
b(T) = b_0 + (T - T_0)\nu,
\]

(1)

where \( b_0 \) is the barycentric position at the initial epoch \( T_0 \)
and \( \nu \) the constant space velocity. The model has six kinematic pa-
rameters, namely the components of vectors \( b_0 \) and \( \nu \) in the
barycentric reference frame. The conditions of applicability of
this model are considered in Appendix E.

An equivalent form of Eq. (1) is obtained by considering two
distinct moments of time, distinguished by subscript 1 and 2:

\[
b(T_2) = b(T_1) + (T_2 - T_1)\nu.
\]

(2)

As emphasized in the introduction, we work here in a
special-relativistic framework since all the effects of general rel-
ativity can be assumed to have been taken into account in the
reduction from measurable (proper) directions to coordinate di-
rections, as comprehensively discussed by Klioner (2003). From
here on, by observation we mean the information about the in-
stantaneous position and velocity of a star as seen by an observer
This fact suggests that we need to recognize the difference between observable quantities, such as \( \mathbf{b}(T_{\text{obs}}) \) at time \( T_{\text{obs}} \), and those that cannot be directly observed, such as \( \mathbf{b}(T_{\text{em}}) \). We shall refer to the observable quantities as apparent, while the unobservable quantities are referred to as true. Thus we may write

\[
\mathbf{b}^{\text{app}}(T_{\text{obs}}) \equiv \mathbf{b}^{\text{true}}(T_{\text{em}}) \quad [ \equiv \mathbf{b}(T_{\text{em}}) ].
\]  

The bracketed equality emphasizes that the quantities considered up until now have all been true in the above sense.

The uniform rectilinear model in Eq. (1) or (2) is of course expressed entirely in terms of true quantities. We shall now re-write it in terms of apparent quantities at the times of observations. Since \( \tau = \mathbf{b}^{\text{app}}(T_{\text{obs}}) / c \) we consider the light-time \( \tau \) to be an observable (apparent) quantity.

If \( T_1 \) and \( T_2 \) in Eq. (2) are taken to be the times of emission we can write

\[
\mathbf{b}^{\text{true}}(T^2_{\text{em}}) = \mathbf{b}^{\text{true}}(T^1_{\text{em}}) + (T^2_{\text{em}} - T^1_{\text{em}}) \mathbf{v}^{\text{true}}.
\]  

Using Eq. (6) to re-write the left-hand side, and Eq. (5) to express \( T^2_{\text{em}} - T^1_{\text{em}} \) in terms of observable quantities, we find

\[
\mathbf{b}^{\text{app}}(T^2_{\text{obs}}) = \mathbf{b}^{\text{app}}(T^1_{\text{obs}}) + \left[ (T^2_{\text{obs}} - T^1_{\text{obs}}) (\tau_2 - \tau_1) \right] \mathbf{v}^{\text{true}}.
\]  

This almost achieves our goal, except that the formula still contains one quantity, \( \mathbf{v}^{\text{true}} \), that cannot be directly observed.

The (true) velocity is by definition the time derivative of the position vector, as is also evident from Eq. (1). It does not matter whether we use the time of emission or observation when calculating the derivative, as long as the same time is used as argument of the position vector being differentiated; that is

\[
\mathbf{v}^{\text{true}} = \frac{d\mathbf{b}^{\text{true}}(T_{\text{em}})}{dT_{\text{em}}} = \frac{d\mathbf{b}^{\text{true}}(T_{\text{obs}})}{dT_{\text{obs}}}.
\]  

Actually, none of these derivatives can be directly measured. The only velocity that can, in principle, be obtained directly from observations is the derivative of the apparent position with respect to the time of observation, or

\[
\mathbf{v}^{\text{app}} = \frac{d\mathbf{b}^{\text{app}}(T_{\text{obs}})}{dT_{\text{obs}}}.
\]  

Comparison with Eq. (11) shows that the velocities are related through

\[
\mathbf{v}^{\text{app}} = \mathbf{v}^{\text{true}} \frac{dT_{\text{em}}}{dT_{\text{obs}}}.
\]  

To proceed, we need expressions for these derivatives such that \( dT_{\text{em}} / dT_{\text{obs}} \) is written as a function of the true velocity, while \( dT_{\text{obs}} / dT_{\text{em}} \) is written as a function of the apparent velocity.

These expressions are obtained from the light-time equation (5). Differentiating with respect to \( T_{\text{em}} \) gives

\[
\frac{dT_{\text{obs}}}{dT_{\text{em}}} = 1 + \frac{\mathbf{v}^{\text{true}}}{c}.
\]  

where we have defined the true radial velocity\(^1\) as the derivative of the (true) barycentric distance with respect to the time of light emission,

\[
v^{\text{true}} = \left. \frac{d\mathbf{b}^{\text{true}}(T)}{dT} \right|_{T=T_{\text{em}}}.
\]  

\(^1\) Called “kinematic radial velocity” in Lindegren & Dravins 2003.
By writing \( \mathbf{b} = \mathbf{u} b \), where \( \mathbf{u} \) is a unit vector, we have \( \partial b / \partial T = \mathbf{u} \partial (\mathbf{b} / \partial T) \), from which it follows that \( v_r^{\text{true}} \) is the projection of \( v_r^{\text{true}} \) along the line-of-sight \( u^{\text{true}}(T^{\text{em}}) = u^{\text{app}}(T^{\text{obs}}) \).

The expression for \( \partial T^{\text{obs}} / \partial T^{\text{em}} \) is obtained in a similar way. Differentiating Eq. (4) with respect to \( T^{\text{obs}} \), while using Eq. (6), gives

\[
\frac{\partial T^{\text{em}}}{\partial T^{\text{obs}}} = 1 - v_r^{\text{app}} / c , \tag{15}
\]

where we have defined the apparent radial velocity \( v_r^{\text{app}} \) as the derivative of the (apparent) barycentric distance with respect to the time of observation,

\[
v_r^{\text{app}} = \frac{\partial b^{\text{app}}(T)}{\partial T} \bigg|_{T=T^{\text{obs}}} . \tag{16}
\]

It is readily verified that \( v_r^{\text{app}} \) is the projection of \( \mathbf{v}^{\text{app}} \) along the line-of-sight \( u^{\text{app}} \) at the time of observation.

Substituting Eqs. (13) and (15) into Eqs. (11) and (12), respectively, we obtain the transformations between the apparent and true velocities

\[
v_r^{\text{true}} = (1 + v_r^{\text{true}} / c)^{-1} v_r^{\text{true}} \tag{17},
\]

\[
v_r^{\text{true}} = (1 - v_r^{\text{app}} / c)^{-1} v_r^{\text{app}} . \tag{18}
\]

Thus, the velocities are related through the Doppler factor (or its inverse); the directions of the apparent and true velocities are the same, while their absolute values are different.

While the true velocity is constant, according to the uniform rectilinear model, its radial component \( v_r^{\text{true}} = \mathbf{u}(T) v_r^{\text{true}} \) in general changes gradually as the star moves along a straight line because of the changing line-of-sight direction \( u(T) \). As shown by Eq. (17) this means that the apparent velocity, in general, is also a function of time. The exception is for a star without proper motion, i.e. moving along a straight line passing through the observer, in which case the true radial velocity is constant.

We are now in position to write down the kinematic model entirely in terms of apparent quantities. Inserting Eq. (18) in (5) we obtain:

\[
\mathbf{b}^{\text{app}}(T_2^{\text{obs}}) = \mathbf{b}^{\text{app}}(T_1^{\text{obs}}) + \left[ (T_2^{\text{obs}} - T_1^{\text{obs}}) - (T_2 - T_1) \right] \frac{\mathbf{v}^{\text{app}}}{1 - v_r^{\text{app}} / c} . \tag{19}
\]

As already mentioned, the apparent velocities \( \mathbf{v}^{\text{app}} \) and \( v_r^{\text{app}} \), which appear in the final factor of Eq. (19), are in general functions of time. However, since this factor equals the true velocity, which is independent of time, it can be evaluated for any time including \( T_1^{\text{obs}} \) and \( T_2^{\text{obs}} \).

Equation (19), governing the apparent path of the star, is fundamental for calculating the apparent quantities at an arbitrary moment of time. We discuss its solution in Sect. 5. The classical path equation (3) is recovered in the limit as \( c \to \infty \).

---

2 The expression on the right-hand side of Eq. (13) is sometimes referred to as the “Doppler factor” (e.g. Stumpf 1985). The name derives from the circumstance that in the classical approximation it equals the ratio of observed to rest-frame wavelengths, \( \lambda_{\text{obs}} / \lambda_{\text{lab}} \), for a non-moving observer. In special relativity the wavelength ratio remains an additional (Lorentz) factor due to the different rates of \( T^{\text{em}} \) and the proper time at the star; this factor depends on the total velocity \( v_{\text{true}} \), and therefore involves its tangential component as well as the radial.

3 Called “astrometric radial velocity” in Lindegren & Dravins (2003).

---

4. Astrometric parameters

In this section, we define the astrometric parameters complying with the kinematic model described above and introduce the corresponding notations.

The instantaneous kinematic state of the star in the barycentric frame is conventionally specified by means of six parameters. All six parameters can, at least in principle, be derived from observations made from a platform in orbit around the solar system barycentre, such as the Earth or a satellite. The parameters are therefore observable or apparent in the sense discussed above, and they refer to the time of observation \( T^{\text{obs}} \).

From here on, nearly all quantities discussed in this paper are in fact apparent, and the time used is that of the observation. For brevity, we can therefore omit the subscripts “true”, “app”, “em”, and “obs” in most equations, and only use them where they are needed to avoid ambiguity. Their absence thus implies an apparent or observed quantity.

Five of the six astrometric parameters are the classical parameters: right ascension \( \alpha \), declination \( \delta \), trigonometric parallax \( \sigma \), proper motion in right ascension \( \mu_{\alpha} \), and proper motion in declination \( \mu_{\delta} \). The sixth parameter could be the “astrometric radial velocity” \( v_r \) (Lindegren & Dravins 2003), equivalent to the “apparent radial velocity” of Klioner (2003), but for reasons that will become clear later we prefer to use the “radial proper motion” \( \mu_r = v_r \sigma / A \) (Lindegren et al. 2012). Here \( A \) is the astronomical unit (IAU 2012). All six parameters are barycentric in the sense that they are derived from observations, which by necessity are non-barycentric, through the application of various corrections, so that they effectively refer to a fictitious observer at the barycentre. Similarly \( T \) is the (fictitious) time of light reception at the barycentre. For the precise definition of the parameters in a general-relativistic framework and an exposition of the relevant corrections, we refer to Klioner (2003). For stellar observations, the end result of this process is a set of astrometric parameters that, to sufficient accuracy, can be interpreted in a completely classical way, as we do in this paper (cf. Appendix E). The timescale for \( T \) is barycentric coordinate time, TCB.

The six astrometric parameters \( \alpha, \delta, \sigma, \mu_{\alpha}, \mu_{\delta}, \mu_r \) change continuously with \( T \) due to the space motion of the star. Therefore, a “reference epoch” \( T_0 \) must be chosen, purely as a matter of convention, and we shall subsequently use \( t = T - T_0 \) as the time argument in all expressions instead of \( T \). Furthermore, to simplify the expressions we often omit the time argument but use subscript 0 to denote quantities at \( t = 0 \) and the corresponding unsubscripted variables when they refer to an arbitrary \( t \).

We shall now give a precise definition of the six astrometric parameters in terms of the quantities introduced in Sect. 3. The barycentric vector \( \mathbf{b} \) is not directly observable but barycentric coordinate direction, given by the unit vector

\[
u = \frac{\mathbf{b}}{|\mathbf{b}|} , \tag{21}
\]

is observable, and so is its time derivative, the proper motion vector

\[
\mu = \frac{d\mathbf{u}}{dt} . \tag{22}
\]

Both are normally expressed in the ICRS. Although these vectors together have six coordinate components, they must at any time
satisfy two scalar constraints, namely \( u'u = 1 \) and \( u'\mu = 0 \), and so have four degrees of freedom. They correspond to the four astrometric parameters \( \alpha, \delta, \mu_\alpha, \) and \( \mu_\delta \). To obtain the first two parameters, let \( r \) be a fixed unit vector coinciding with \( u \) at the given time \( t \). Its coordinates in ICRS are

\[
r = \left( \frac{\cos \delta \cos \alpha}{\sin \delta}, \frac{\cos \delta \sin \alpha}{\sin \delta} \right),
\]

(23)

from which \( \alpha \) and \( \delta \) are obtained\(^4\). However, while \( r \) is uniquely given by \( \alpha \) and \( \delta \), the reverse is not true: any given \( r \) can be represented by an infinite set of \((\alpha, \delta)\) pairs. Restricting their ranges (e.g. \( 0 \leq \alpha < 2\pi \) and \( -\pi/2 \leq \delta \leq \pi/2 \)) removes most of the ambiguity, but in the special cases of \( \delta = \pm \pi/2 \) (exactly) the choice of \( \alpha \) is still arbitrary. Nevertheless, a choice must be made, as it determines the subsequent calculation of the proper motion components \( \mu_\alpha \) and \( \mu_\delta \) from \( \mu \). Given \( \alpha \) and \( \delta \) we can calculate the unit vectors in the directions of increasing right ascension and declination, which are

\[
p = \left( -\frac{\sin \alpha}{\cos \delta}, 0 \right), \quad q = \left( -\frac{\sin \delta \cos \alpha}{\sin \delta}, -\frac{\sin \delta \sin \alpha}{\sin \delta} \right),
\]

(24)

respectively. Equations (23)–(24) define three orthogonal unit vectors forming the so-called normal triad \((p, q, r)\) at \( r \) relative to the celestial reference frame (Murray 1983). We now define the proper motion components as the coordinates of \( p \) along the \( p \) and \( q \) axes, or

\[
\mu_\alpha = p'\mu, \quad \mu_\delta = q'\mu.
\]

(25)

Conversely, since \( r'\mu = 0 \), the proper motion vector can be reconstructed as

\[
\mu = p\mu_\alpha + q\mu_\delta.
\]

(26)

We note that the procedure above allows us to calculate the proper motion components even when \( \delta \equiv \pm \pi/2 \), using the arbitrary chosen value of \( \alpha \): the latter defines the directions of the \( p \) and \( q \) vectors according to Eq. (24) and therefore the resulting values of \( \mu_\alpha \) and \( \mu_\delta \) from Eq. (25).

An alternative interpretation of the proper motion components is

\[
\mu_\alpha = \frac{\partial r}{\partial t} \cos \delta, \quad \mu_\delta = \frac{\partial \delta}{\partial t},
\]

(27)

It is readily verified that this is equivalent to Eq. (25) when \( |\delta| < \pi/2 \), but at the celestial poles it obviously fails. We therefore regard Eq. (25) as the more general interpretation.

Stellar parallax is sometimes defined as the angle subtended by 1 au at the star’s distance from the Sun (e.g. Murdin 2001). Interpreting “distance” to mean the coordinate distance between \( b \) and \( b_0 \) from the solar system barycentre, this definition is still ambiguous as to the precise relation to parallax \( \alpha \); it could be sin \( \alpha \). (Murray 1983), tan \( \alpha = A/b \) (Binney & Merrifield 1998), or even 2 sin(\( \alpha/2 \) = A/b (if the astronomical unit is the chord of the angle); the differences, of the order of \( \alpha^3 \) < \( 10^{-10} \) arcsec, are truly negligible for all stars. Following Klioner (2003) we adopt the mathematically simplest relation

\[
\alpha = \frac{A}{b},
\]

(28)

\(^4\) The distinction between \( r \) and \( u \) may at first seem pointless or at least over-pedantic. In fact, as explained in Sect. 5.3 it is relevant for the interpretation of the proper motion components and their uncertainties.

which to second order is equivalent to all the alternative expressions. It may seem strange to define parallax, which obviously is an observable quantity, in terms of \( b \), which according to previous discussion is not (directly) observable. However, \( \alpha \) should rather be regarded as a model parameter allowing us to interpret non-barycentric observations in a consistent manner, and Eq. (28) is then the relation to be used in the model for calculating its effect on the data.

From Eq. (20) it is seen that the radial proper motion equals \( \mu_r = v_r/b \). This is analogous to the expression for the total (tangential) proper motion

\[
\mu = (\mu_\alpha + \mu_\delta)^{1/2} = v_r/b \quad \text{or} \quad \mu = v_t/b,
\]

(29)

where \( v_r \) is the apparent (or astrometric) tangential velocity (Sect. 3). The three components of proper motion \( \mu_\alpha, \mu_\delta, \) and \( \mu_r \) are conveniently expressed in the same unit, for example mas yr\(^{-1} \). The unit of time in this case would be the Julian year of exactly 365.25 \times 86400 s (TCB).

It is also useful to note the expression for the (apparent) space velocity in terms of the astrometric parameters:

\[
v = \frac{Av}{\sigma} (r\mu_r + \mu),
\]

(30)

where \( A_v = 4.740470 446 \) equals the astronomical unit expressed in km yr\(^{-1} \). This relation implies that the parallax and proper motions are expressed in compatible units, for instance, mas and mas yr\(^{-1} \), respectively.

5. Epoch transformation including light-time effects

In this section, we develop and summarize the transformation of the astrometric parameters and their covariances with rigorous treatment of the light-travel time effects.

5.1. Solution of the apparent path equation

Equations (8) and (19) implicitly determine the apparent position in terms of the true and apparent velocity, respectively. In subsequent Eqs. (31)–(37) let \( \bar{b} \) denote the true velocity. Using notations introduced in Sect. 4 we can write Eq. (8) as

\[
b = b_0 + \bar{b} (t - \frac{b}{c} + \tau_0),
\]

(31)

where \( t_0 = b_0/c \) is the initial light-time. Squaring both sides we obtain a quadratic equation for the apparent distance:

\[
1 - \left( \frac{v^2}{c^2} \right) b^2 + 2 \frac{v'}{c} \left[ b_0 + \bar{b} (t + \tau_0) \right] b - \left[ b_0 + \bar{b} (t + \tau_0) \right]^2 = 0.
\]

(32)

It is seen from the Viète’s formulae that the roots of this equation are of opposite signs. Choosing the positive root, we find

\[
1 - \left( \frac{v^2}{c^2} \right) b = -\left( \frac{1}{c} \bar{b}' \left[ b_0 + \bar{b} (t + \tau_0) \right] \right)
\]

\[+ \sqrt{ \left[ b_0 + \bar{b} (t + \tau_0) \right]^2 - \frac{1}{c^2} (\bar{b}' \times b_0)^2}.
\]

(33)

The fact that the right-hand side is positive for any position and velocity is easily demonstrated by writing the radicand as the sum of two essentially positive values,

\[
1 - \left( \frac{v^2}{c^2} \right) \left[ b_0 + \bar{b} (t + \tau_0) \right]^2 + \frac{1}{c^2} \left[ \bar{b}' \left[ b_0 + \bar{b} (t + \tau_0) \right] \right]^2.
\]

(34)

Article number, page 5 of 18
one of them is exactly equal to the square of the first term in the right-hand side.

Having determined the propagated apparent distance, we can calculate the expression in parenthesis in equation (31), which is the difference in the emission time corresponding to the time interval \( t \), according to formula (8):

\[
\Delta T_{\text{em}} = t - \frac{b}{c} + \tau_0 .
\]

(35)

Making use of \( b \) from Eq. (13), we get

\[
\left(1 - \frac{v^2}{c^2}\right) \Delta T_{\text{em}} = t + \tau_0 + \frac{\bar{v} b_0}{c^2} - \frac{1}{c} \left[\bar{v} (t + \tau_0)\right]^2 - \frac{1}{c^2} \left(\bar{v} \times b_0\right)^2.
\]

(36)

It is convenient for the following development to represent \( \Delta T_{\text{em}} \) as a fraction using the identity \( x - y = (x^2 - y^2)/(x + y) \):

\[
\Delta T_{\text{em}} = t (t + 2\tau_0) \times \left[1 + \frac{v b_0}{c^2} - \frac{1}{c} \left[\bar{v} (t + \tau_0)\right]^2 - \frac{1}{c^2} \left(\bar{v} \times b_0\right)^2\right]^{-1}.
\]

(37)

Substituting \( \bar{v} = v_0/(1 - v_0/c) \) according to Eq. (15) and inserting the resulting expression for \( \Delta T_{\text{em}} \) into Eq. (19) we finally obtain, after elementary, though rather lengthy calculations,

\[
b = b_0 + v_0 f_T \times \tau_0 + \left[1 - \frac{v_0}{c}\right] t + \frac{1}{c} \left[\bar{v}_0 + v_0 f_T\right]^2 + \frac{2\tau_0}{c^2} (v_0 \times b_0)^2
\]

(39)

These formulae give the complete solution to the problem: they determine the apparent position at any instant in terms of the given initial apparent position and velocity.

It is instructive to consider briefly the special case of purely radial motion when \( v_{\theta} = v_0 = 0 \). Then, \( v_0 b_0 = v_0 b_0 = 0 \), so that \( f_T = 1 \) and Eq. (38) simplifies to

\[
b = b_0 + v_0 f_T .
\]

(40)

Thus, we conclude that the finite light-travel time has no effect on the apparent stellar motion in the case of purely radial motion. Of course, this result can be obtained much more simply without using the general solution of the apparent path equation: noting that both \( v_{\text{true}}^T \) and \( v_{\text{true}}^\perp \) are constant in this case, it follows from Eq. (17) that the apparent velocity is also constant. Thus, we can replace the differentials in Eqs. (11) and (12) with finite differences to find

\[
\Delta T_{\text{em}} v_{\text{true}} = \Delta T_{\text{obs}} v_{\text{app}} .
\]

(41)

Substituting this in Eq. (17) and using the relation (5) between the true and apparent positions, we again arrive at Eq. (40). Since light-time effects thus vanish in the absence of transverse motion, they can be expected to be small for stars with small proper motions. We address this question further in Appendix I.

5.2. Propagation of the astrometric parameters

The solution (33) gives the time dependence of the apparent position, which, in turn, determines propagation of the barycentric direction and parallax, defined by Eqs. (21) and (29), respectively. Squaring both sides of Eq. (39) we find

\[
b^2 = b_0^2 \left(1 + 2 \mu_0 f_T + \left(\mu_0^2 + \mu_0^2\right) (t f_T)^2\right).
\]

(42)

Here, we used that \( b_0^2 = b_0^2 \mu_0 \) and \( v_0^2 = b_0^2 \left(\mu_0 + \mu_0^2\right)\), as is easily seen from Eqs. (21), (29), and (39).

Introducing the distance factor

\[
f_0 = b_0/b = \left[1 + 2 \mu_0 f_T + \left(\mu_0^2 + \mu_0^2\right) (t f_T)^2\right]^{-1/2},
\]

(43)

the propagation of the barycentric direction is

\[
u = |u_0| (1 + \mu_0 f_T + \mu_0 f_T) f_0
\]

(44)

and the propagation of the parallax becomes

\[
\varpi = \varpi_0 f_0 .
\]

(45)

The celestial coordinates \((\alpha, \delta)\) at epoch \(t\) are obtained from \(u\) in the usual manner, using Eq. (23).

We now consider the propagation of the proper motions \(\mu\) and \(\mu_0\). It is clear from the above discussion that the proper motions can be found by two equivalent methods. They can be either expressed as the time derivatives or obtained from relevant velocity components. The direct differentiation with respect to time, however, offers great difficulties since \(u\) and \(b\) involve the factor \(f_T\), which is a complicated function of time. On the contrary, the calculation of the proper motion using the apparent velocity is relatively simple in the present case.

To find the propagated apparent velocity, it is convenient to employ the following artifice taking advantage of the postulated constancy of the true velocity. We first obtain the true velocity from the initial apparent velocity using Eq. (15) and then substitute the true velocity in Eq. (17) to get the apparent velocity at the time \(t\). However, it should be emphasized that the radial component of the true velocity \(v_{\text{true}}^r\) in (17) must be computed along the propagated barycentric direction: \(v_{\text{true}}^T = u v_{\text{true}}\). Carrying out the calculation, we find the propagated apparent velocity

\[
v = v_0 f_T ,
\]

(46)

where we have introduced the velocity factor

\[
f_T = \left[1 + \frac{u v_0}{c} - \frac{v_0}{c}\right]^{-1} = \left[1 + \frac{(u - u_0) v_0}{c}\right]^{-1} .
\]

(47)

Decomposition of \(v\) into the components normal and along the propagated direction yields propagation of the transverse and radial components of the apparent velocity, which are

\[
v_\parallel = [v_0 - u (u v_0)] f_T ,
\]

(48)

\[
v_\perp = (u v_0) f_T ,
\]

(49)

respectively. Substitution of these relations in Eqs. (20) and (29) gives the propagation of the proper motions:

\[
\mu = \mu_0 \left[1 + \mu_0 f_T - u_0 Q_0 f_T\right] f_T^{-1} f_T ,
\]

(50)

\[
\mu_0 = \mu_0 + \left(\mu_0^2 + \mu_0^2\right) (t f_T)^2 f_T^{-1} f_T .
\]

(51)

To obtain the proper motion components \((\mu_\alpha, \mu_\delta)\) from vector \(\mu\) it is necessary to resolve the latter along the tangential vectors \(p\).
and \( q \), using Eq. (53). The tangential vectors are defined in terms of the propagated \( u \) or \((\alpha, \delta)\) at epoch \( t \) according to Eq. (24).

The above formulae describe the complete transformation of \((\alpha_0, \delta_0, \varpi_0, \mu_{\alpha 0}, \mu_0, \mu_\delta)\) at epoch \( T_0 \) into \((\alpha, \delta, \varpi, \mu_\alpha, \mu_\delta, \mu)\) at the arbitrary epoch \( T = T_0 + t \), including the light-time effects. The transformation is rigorously reversible: a second transformation from \( T \) to \( T_0 \) recovers the original six parameters.

5.3. The scaling factors \( f_0, f_\tau, \text{and} f_\nu \)

The propagation formulae derived in the preceding sections involve three quantities \( f_0, f_\tau, \text{and} f_\nu \), which appear as scaling factors for the changes in (apparent) distance, time, and velocity over the propagated interval. In this section, we further examine their physical meaning and give their expressions in terms of the astrometric parameters.

All three factors are in practice very close to unity, linearly approaching 1 as \( t \rightarrow 0 \). (Approximate formula for small \( t \) are derived in Appendix B.) While \( f_\nu = f_\tau = 1 \) in the limit as \( c \rightarrow \infty \), the distance factor \( f_0 \) in general deviates from 1 when light-time effects are ignored (cf. Sect. 5.5), as it gives the relative change in distance according to Eq. (43).

The meaning of the time factor \( f_\tau \) is not immediately evident from its derivation in Sect. 5.1. However, noting that it can also be written

\[
f_\tau = \frac{1}{1 - \Delta T_0/c} \frac{\Delta T_{\text{cm}}}{\Delta T_{\text{obs}}} ,
\]

we see that it represents the combination of two physical effects originating from the finiteness of the speed of light: the difference between time of observation and time of emission, and the difference in the absolute value between the true and apparent velocities (the Doppler factor). Writing the initial light-time as

\[
t_0 = \tau_A / \varpi_0 ,
\]

with \( \tau_A = A/c = 499,004,784 \) s being the light-travel time for the astronomical unit, we can express the time factor in terms of the astrometric parameters:

\[
f_\tau = \frac{\varpi_0 t + 2 \tau_A}{\varpi_0 t + \tau_A (1 + Z - \mu_{\alpha 0})} ,
\]

where

\[
Z = \sqrt{1 + (t + 2 \tau_A / \varpi_0) \mu_{\alpha 0}^2 + (2 + \mu_{\alpha 0}) \mu_\delta} .
\]

As shown by Eq. (46), the velocity factor \( f_\nu \) yields the relative change in apparent velocity over the time interval of propagation. From the second equality in Eq. (47), this effect can be understood as a secular change of the Doppler factor. In terms of the astrometric parameters, the velocity factor can be written as

\[
f_\nu = \left( 1 + (\alpha_0 / \varpi_0) [\mu_\delta (f_\nu - 1) + f_0 (\mu_\alpha^2 + \mu_\delta^2) f_\tau] \right)^{-1} .
\]

Finally, we note that the factors \( f_\nu \) and \( f_\tau \) are connected by the following remarkably simple relation:

\[
f_\nu = \frac{d}{dt} (tf_\tau) .
\]

While a direct check of this relation involves cumbersome calculations, it can be verified more easily by comparing the expression for the proper motion vector in Eq. (50) with the equivalent vector obtained by differentiating \( u \) in Eq. (44) with respect to \( t \). The meaning of Eq. (57) becomes clearer if it is re-written in the following way. Substituting Eq. (52) for the time factor, using that \( \Delta T_{\text{obs}} = t \), and making use of Eqs. (46), (55), and (16), we obtain the following equivalent form of Eq. (57):

\[
\frac{\nu}{\nu_0} = \frac{1 - \nu_\ell/c}{1 - \nu_{\ell 0}/c} .
\]

This equation has a simple interpretation: it gives the explicit relation between the absolute value of the propagated apparent velocity and the propagated apparent radial velocity. In particular, it shows that these quantities vary in opposite directions: an increasing \( \nu_\ell \) results in a decreasing \( \nu \) and vice versa. A qualitatively similar behaviour is found in cases when the motion does not obey the uniform rectilinear model; however, the simple linear relation above does not hold in general.

5.4. Propagation of errors (covariances)

In this section we consider how uncertainties in the astrometric parameters \( \alpha_0, \delta_0, \varpi_0, \mu_{\alpha 0}, \mu_\delta, \mu_0 \) at epoch \( T_0 \) propagate into uncertainties in the transformed parameters \( \alpha, \delta, \varpi, \mu_\alpha, \mu_\delta, \mu \) at epoch \( T = T_0 + t \). The uncertainties are quantified by means of the \( 6 \times 6 \) covariance matrices \( C_0 \) and \( C \) in which the rows and columns correspond to the astrometric parameters taken in the order given above.

The general principle of (linearized) error propagation is well known and we refer to Appendix A for a brief introduction including an illustrative example. Essentially, it requires the calculation of all 36 partial derivatives constituting the elements of the Jacobian matrix \( J \) in Eq. (A.3), such that

\[
C = J C_0 J' .
\]

The required partial derivatives are readily found once the relations between the corresponding differentials have been established, i.e. the first-order propagation of small perturbations of the parameters. We give below the complete derivation of these differentials since it may be of some methodological interest. The subsequent determination of the partial derivatives is straightforward, if somewhat tedious, and the full results are given in Appendix B.

At this point we need to make one further remark concerning the propagation of perturbations. The components of proper motion are obtained by resolving the proper motion vector \( \mu \) according to Eq. (25), that is \( \mu_{\alpha 0} = p' \mu_\alpha \) and \( \mu_\delta = q' \mu_\delta \). Here, the tangential vectors \( p \) and \( q \) are defined by Eq. (24) in terms of the barycentric position \((\alpha, \delta)\) of the star at the relevant epoch. Consider now what happens when both the position and proper motion vectors receive small perturbations \( \Delta \mu \) and \( \Delta \mu \). The perturbation in position clearly affects \( \alpha \) and \( \delta \), and the question arises if this also changes \( p \) and \( q \). If that is the case, then the total perturbations on the proper motion components become

\[
\Delta \mu_{\alpha 0} = p' \Delta \mu + \Delta p' \mu , \quad \Delta \mu_\delta = q' \Delta \mu + \Delta q' \mu ,
\]

where \( \Delta p \) and \( \Delta q \) are the perturbations on the tangential vectors induced by \( \Delta \mu \). The problem here is that the expressions for \( \Delta p \) and \( \Delta q \) contain the factors sec \( \delta \) and tan \( \delta \) and therefore may become arbitrarily large sufficiently close to the celestial poles. In terms of the uncertainties in \( \mu_{\alpha 0} \) and \( \mu_\delta \) it means that they contain contributions that are unrelated to the actual uncertainty of the proper motion vector, and which in principle are unbounded.

Alternatively, it is possible to regard \( p \) and \( q \) as a fixed, error-free reference frame for perturbations in the tangential plane.
In this case, we must put $\Delta \mathbf{p} = \Delta \mathbf{p} = 0$ in Eq. (60) and all similar expressions. This leads to simpler propagation formulae and an intuitively more reasonable interpretation of the proper motion uncertainties (Lindegren 1995). This option was adopted for the construction of the Hipparcos and Tycho catalogues (cf. Sect. 1.5.5 in Vol. 1 of ESA 1997) and is also used in the following. The practical consequence is that the normal triad $[p \ q \ r]$ must be regarded as fixed in the context of perturbations and uncertainties. The triad is conventionally defined by the adopted values of $(\alpha, \delta)$. This also motivates the formal distinction between $r$ and $u$ referred to in footnote 4.

Summarizing in terms of the local coordinate triads, we may say that the calculations below are based on the following postulates: (i) $[p_0, q_0, r_0]$ is fixed in space and time and does not depend on the uncertainties of the astrometric parameters; (ii) $[p, q, r]$ depends on time through the propagated position $u$ as $r = u$; and (iii) at any moment of time, $[p, q, r]$ is fixed in space and does not depend on the uncertainties of the initial astrometric parameters.

Accordingly, if the coordinates receive small perturbations $\Delta \alpha \ast_0$ and $\Delta \delta_0$, then the perturbed barycentric direction becomes

$$ u_0 + \Delta u_0 = p_0 \Delta \alpha \ast_0 + q_0 \Delta \delta_0 + r_0 \left[ 1 - (\Delta \alpha \ast_0)^2 - (\Delta \delta_0)^2 \right]^{1/2} \ (61) $$

where $\Delta \alpha \ast_0 = \Delta \delta_0 = 0$ corresponds to the nominal position. The quadratic terms follow from the constraint $|u_0 + \Delta u_0| = 1$. Taking the time derivative and using the definitions (22) and (25), we have

$$ \mu_0 + \Delta \mu_0 = p_0 \Delta \alpha \ast_0 + q_0 \Delta \delta_0 - r_0 \left[ 1 - (\Delta \alpha \ast_0)^2 - (\Delta \delta_0)^2 \right]^{1/2} \ (62) $$

This equation suggests that the full differential of the proper motion vector as a function of the initial coordinates and proper motion components is

$$ \text{d} \mu_0 = \left[ -r_0 (\mu_0 \Delta \alpha \ast_0 + \mu_0 \Delta \delta_0) \right] \left[ 1 - (\Delta \alpha \ast_0)^2 - (\Delta \delta_0)^2 \right]^{1/2} + \mu_0 \text{d} \ln f_D \ + \ p_0 \text{d} \mu_0 + q_0 \text{d} \mu_0 \ . \ (63) $$

The terms in $\Delta \alpha \ast_0$ and $\Delta \delta_0$, which are normal to $\mu_0$, lend themselves to a straightforward geometrical interpretation.

The propagated astrometric parameters depend on the scaling factors $f_D, f_T$ and $f_V$, which in turn are functions of the initial parameters. Thus, the dependence of the propagated parameters on the initial parameters becomes quite involved. To keep the expressions compact, we do not expand the differentials of the scaling factors in what follows and give the complete expressions for them later in this section. Moreover, it is convenient to employ the logarithmic differentials rather than ordinary differentials: $\text{d} \ln f_D = \text{d} f_D / f_D$, etc.

We begin with the differentials of the propagated astrometric parameters. Direct differentiation of Eq. (25) yields

$$ \text{d} u = \text{d} \alpha \ast + q \text{d} \delta \ . \ (64) $$

Taking the dot products of this equation with $p$ and $q$, we get

$$ \text{d} \alpha \ast = p \text{d} u \ , \ \text{d} \delta = q \text{d} u \ . \ (65) $$

From Eq. (45) we have

$$ \text{d} \sigma = f_D \text{d} \sigma_0 + \sigma \text{d} \ln f_D \ , \ (66) $$

while (25) yields

$$ \text{d} \mu_\ast = \text{d} \mu \ . \ \text{d} \mu_0 = q \text{d} \mu \ . \ (67) $$

Direct differentiation of Eq. (51) gives

$$ \text{d} \mu_T = 2 tf_f f_T f_V (\mu_{00} \text{d} \mu_{00} + \mu_{00} \text{d} \mu_0) $$

$$ + (1 + 2 \mu_{00} f_T f_V) f_T f_V \text{d} \mu_0 $$

$$ + \mu_T (2 \text{d} \ln f_D + \text{d} \ln f_V + \text{d} \ln f_T) - \mu_0 f_T f_V \text{d} \ln f_T \ . \ (68) $$

The determination of the differentials of the coordinates and proper motion components from Eqs. (65) and (67), respectively, requires $\text{d} u$ and $\text{d} \sigma$ to be written in terms of the initial parameters. From Eq. (44) we have

$$ \text{d} u = [(1 + \mu_{00} f_T f_V) f_T f_V \text{d} \mu_0 + f_T (\text{d} \mu_0 + r_0 \text{d} \mu_0)] f_D $$

$$ - r_0 f_D \text{d} \ln f_T + u \text{d} (f_D + \text{d} \ln f_T) \ . \ (69) $$

It is useful to note that the last term disappears when taking the dot products with $p$ and $q$, since $p' u = q' u = 0$; hence it does not contribute to the differentials $\text{d} \alpha \ast$ and $\text{d} \delta$. Direct differentiation of Eq. (50) yields

$$ \text{d} \mu = -\mu_0^2 f_T f_V f_V \text{d} \mu_0 + (1 + \mu_{00} f_T f_V) f_T f_V \text{d} \mu_0 $$

$$ - 2 r_0 f_T f_V f_V (\mu_{00} \text{d} \mu_0 + \mu_0 \text{d} \mu_0) $$

$$ + \mu_0 f_T f_V \text{d} \mu_0 + \mu_T (3 \text{d} \ln f_D + \text{d} \ln f_V + \text{d} \ln f_T) $$

$$ - \mu_0 f_T f_V \text{d} \ln f_T \ . \ (70) $$

Here we leave the differentials $\text{d} \mu_0$ (analogous to Eq. (64)) and $\text{d} \mu_0$ (from Eq. (65)) unexpanded to avoid too lengthy expressions. We use these expressions in the calculation of the partial derivatives listed in Appendix B.

Finally, we consider the three scaling factors and start with the distance factor. From the definition (43) we find

$$ \text{d} f_D = -(f_T^2 f_V^2 \mu_0 (\mu_{00} \text{d} \mu_{00} + \mu_{00} \text{d} \mu_0) $$

$$ - t f_T f_V^2 (1 + \mu_{00} f_T f_V) \text{d} \mu_0 $$

$$ - f_D^3 \left[ \mu_{00} + (\mu_0^2 + \mu_T^2) f_T^2 f_V \right] f_T \text{d} \ln f_D \ . \ (71) $$

Making use of the propagated radial proper motion given by Eq. (51), we can write the last term as $-f_D (\mu_{00} f_T f_V / f_V) \text{d} \ln f_T$. Dividing by $f_D$, we obtain the logarithmic differential

$$ \text{d} \ln f_D = -(t f_T f_V^2 f_D \mu_{00} (\mu_{00} \text{d} \mu_{00} + \mu_{00} \text{d} \mu_0) $$

$$ - t f_T f_V^2 (1 + \mu_{00} f_T f_V) \text{d} \mu_0 $$

$$ - (\mu_{00} f_T / f_V) \text{d} \ln f_T \ . \ (72) $$

The logarithmic differential of the velocity factor is obtained from Eq. (57) by a straightforward calculation:

$$ \text{d} \ln f_V = \frac{-\frac{T \alpha}{\sigma_0} f_V}{\sigma_0} \left[ \mu_{00} (f_D - 1) + f_0 \left( \mu_0^2 + \mu_T^2 \right) f_T \text{d} \sigma_0 \right. $$$$ - 2 \frac{T \alpha}{\sigma_0} t f_T f_D f_V (\mu_{00} \text{d} \mu_{00} + \mu_{00} \text{d} \mu_0) $$

$$ \left. + \frac{T \alpha}{\sigma_0} f_V (1 - f_D) (1 + 2 \mu_{00} f_T f_V) \text{d} \mu_0 \right) $$

$$ - (\mu_{00} f_T / f_V) \text{d} \ln f_D $$

$$ - \frac{T \alpha}{\sigma_0} f_D f_V (\mu_0^2 + \mu_T^2) f_T f_V \text{d} \ln f_T \ . \ (73) $$

Substituting $\text{d} \ln f_D$ from Eq. (72), we find

$$ \text{d} \ln f_V = \frac{1}{\sigma_0} (1 - f_V) \text{d} \sigma_0 $$

$$ + \frac{T \alpha}{\sigma_0} t f_T f_D (\mu_{00} f_T - 2 f_V) (\mu_{00} \text{d} \mu_{00} + \mu_{00} \text{d} \mu_0) $$

$$ + \frac{T \alpha}{\sigma_0} f_V (f_T + f_D (1 + \mu_{00} f_T f_V) \mu_{00} f_T f_V - 2 f_V) \text{d} \mu_0 $$

$$ - \frac{T \alpha}{\sigma_0} f_D f_V \mu_0 f_T f_D f_V \text{d} \ln f_T \ . \ (74) $$

Article number, page 8 of 13
The time factor is conveniently represented as the fraction
\[ f_t = \frac{X}{Y} \]
with \( X \) and \( Y \) defined by Eq. (54). Then
\[ d \ln f_t = \frac{dX}{X} - \frac{dY}{Y} , \]
where
\[ dX = t d\sigma_0 \]
and
\[ dY = \left( 1 - \frac{\mu_0^2 r^2}{Z \sigma_0^2} \right) d\sigma_0 \]
\[ + \frac{\tau_A}{Z} \left( t + 2 \frac{\tau_A}{\sigma_0} \right) (\mu_{\alpha0} d\mu_{\delta0} + \mu_{\delta0} d\mu_{\alpha0}) \]
\[ + \tau_A \left( 1 + \frac{\mu_0 t}{Z} - 1 \right) d\mu_0 . \]  
(78)

All the required partial derivatives can be derived from the differentials in the formulæ above. As an example, consider the partial derivative of the propagated right ascension with respect to the initial parallax. From Eq. (65) we have
\[ \frac{\partial \alpha}{\partial \sigma_0} = p' \frac{\partial u}{\partial \sigma_0} . \]
(79)

As seen from Eq. (69), the propagated direction \( u \) depends on \( \sigma_0 \) only through the time factor, and we can therefore write
\[ \frac{\partial \alpha}{\partial \sigma_0} = -p' r_0 f_0 \frac{d \ln f_t}{d \sigma_0} . \]
(80)

The terms in Eqs. (77)–(78) containing \( d \sigma_0 \) give
\[ \frac{d \ln f_t}{d \sigma_0} = \frac{t}{X} \left( 1 - \frac{\mu_0^2 r^2}{Z \sigma_0^2} \right) \frac{t}{Y} . \]
(81)

Writing \( X \) and \( Y \) in terms of the astrometric parameters, we finally obtain
\[ \frac{\partial \alpha}{\partial \sigma_0} = -p' r_0 f_0 \left[ \frac{1}{\sigma_0 t + 2 \tau_A} - \frac{1 - \mu_0^2 r^2 / \left( Z \sigma_0^2 \right)}{\sigma_0 t + \tau_A (1 + Z - \mu_0 t)} \right] . \]
(82)

### 5.5. Epoch transformation neglecting light-time effects

Having developed the rigorous formulæ including light-time effects, we now consider the case when light-time effects are not important. This formally corresponds to the limit as \( c \to \infty \), or zero light-travel time. Since all light-time effects have been parametrized with \( \tau_A = A/c \); we can formally exclude them by putting \( \tau_A = 0 \). This substitution gives \( f_t = f_0 = 1 \) and the distance factor
\[ f_D = \left[ 1 + 2 \mu_0 t + \left( \mu_0^2 + \mu_0^3 r^2 \right) \right]^{-1/2} . \]
(83)

The propagated quantities are readily obtained: the barycentric direction
\[ u = \left[ r_0 (1 + \mu_0 t) + \mu_0 t \right] f_D , \]
(84)
the parallax
\[ \sigma = \sigma_0 f_D , \]
(85)
and the proper motion vector
\[ \mu = \frac{du}{dt} = \left[ \mu_0 (1 + \mu_0 t) - r_0 \mu_0 t^2 / f_D \right] f_D^2 , \]
(86)
and the radial proper motion
\[ \mu_r = \frac{db \sigma}{dt} A = \left[ \mu_0 + (\mu_0^2 + \mu_0^3 t) / f_D \right] f_D . \]
(87)

The celestial coordinates (\( \alpha, \delta \)) and proper motion components (\( \mu_\alpha, \mu_\delta \)) at epoch \( t \) are obtained from \( u \) and \( \mu \) in the usual manner using Eqs. (23) and (25), respectively.

These formulæ were employed in the reduction procedures used to construct the Hipparcos and Tycho catalogues, since light-time effects were known to be negligible at milli-arcsecond accuracy (ESA 1997, Vol. 1, Sect. 1.5.5). The transformation described by the above expressions is also rigorously reversible. The corresponding elements of the Jacobian matrix needed to propagate the covariances are given in Appendix [C](#).

### 6. Discussion

In the following, we discuss the conditions under which the light-time effects may be significant when propagating the astrometric parameters of a star from one epoch to another. We consider first the absolute size of the effect itself, and then its size in relation to deviations from the assumed uniform rectilinear motion. The applicability of the developed technique to real data is discussed, and a simple criterion established for when the light-time effects should be ignored. Finally, we briefly review this work in relation to the earlier treatment by Stumpf (1985).

#### 6.1. When is it possible to ignore light-time effects?

In practice, the finite light-time may be ignored if its observable effects are small compared to the required astrometric accuracy. In Appendix [D](#) we derive approximate formulæ for the effects of the light-time on the parameters propagated over the time interval \( t \). Here, we only consider the effects on the angular position, \( \Delta \theta \), and on the proper motion, \( \Delta \mu \). Let \( \sigma_0 \) and \( \sigma_M \) be the required accuracies in position and proper motion. The two
conditions for negligible light-time effects are then $\Delta \theta \ll \sigma_\theta r$ and $\Delta \mu \ll \sigma_\mu$, which by means of Eq. (12.9) can be written

$$i^2 \ll \frac{2\sigma_\mu}{\mu^2 r_\lambda^2}, \quad t \ll \frac{\sigma_\theta}{\mu^2 r_\lambda}.$$  

(88)

If the positions and proper motions are derived from observations around the original epoch we find, in the limit of large $t$, that $\sigma_\mu = \sigma r_\mu$, from Eq. (8.9). In this case the two conditions become essentially the same (within a factor of 2).

The strong (cubic) dependence on $\mu$ in Eq. (88) suggests that light-time effects could mainly be important for high-proper motion stars. As an example, let us consider Barnard’s star (HIP 87937) which, with $\mu = 10357.70$ mas yr$^{-1}$ and $\sigma = 549.01$ mas, has the largest proper motion in the Hipparcos catalogue (ESA 1997). At $\sigma_\theta = 1$ mas position accuracy, light-time effects are negligible for $t \ll 114$ yr. At $\sigma_\mu = 1$ mas accuracy, they are only negligible for $t \ll 3.6$ yr. Figure 2 shows the effects in position and velocity ($\Delta \mu$) as functions of time for this star.

6.2. When is it necessary to ignore light-time effects?

Up until now it has been tacitly assumed that the astrometric parameters exactly describe the state of motion of the star. If this condition is not fulfilled, for example, because of uncertainties in the parameters, a direct application of the simple kinematic model may produce erroneous and even physically absurd results. Clearly, this will happen for negative parallaxes, light-time effects must in fact be ignored under more restrictive conditions.

A simple example illustrates the effect of observational errors. Consider the case when the measured parallax is smaller than the true parallax, while other astrometric parameters have negligible errors. The distance inferred from the measured parallax is then too large, and the transverse velocity calculated from the distance and proper motion is also overestimated. If the true parallax is small, the measured value, while still positive, can be many times smaller than the true parallax, leading to distances and transverse velocities overestimated by a large factor. As the parallax is small, the measured value, while still positive, can be negligibly smaller than the true parallax, while other astrometric parameters have effects must in fact be ignored under more restrictive conditions.

For a star with known parallax, proper motion, and radial velocity the effects of the finite light-time on the propagated astrometric parameters are readily computed from a direct comparison between the rigorous propagation (Sect. 5.2) and when light-time effects are ignored (Sect. 5.5). We have made this computation for Hipparcos stars with radial velocities taken from the XHIP catalogue (Anderson & Franci 2012). The last two columns in Table [1] list the computed effects over a century in position ($\Delta \theta_0$) and in the absolute value of the space velocity ($\Delta v_0$). For the listed 33 entries, these quantities exceed 0.1 mas or 0.1 m s$^{-1}$, respectively. Since $\Delta \theta_0$ increases very nearly quadratically with time, and $\Delta v_0$ increases linearly (cf. Fig. [E]), the values listed in the table for $t = 100$ yr are easily scaled to other epoch differences.

To find the objects listed in Table [1] we computed the effects for all 15 517 objects with a radial velocity in XHIP and $\sigma_\mu > 10\sigma_\mu$ in the Hipparcos catalogue (ESA 1997). It should be noted that the Hipparcos catalogue may contain additional entries where the effects exceed 0.1 mas or 0.1 m s$^{-1}$, but which were excluded because of one of the above criteria.

It is interesting to compare the light-time effect in position with the more well-known perspective acceleration (Schlesinger 1917, van de Kamp 1977, Murray 1983), which is a purely geometrical effect due to the changing distance and angle between the velocity vector and line of sight (it is equivalent to the Coriolis acceleration in the coordinate system rotating with the line of sight). The apparent acceleration due to this effect is $\mu = -2\mu c^2$, which after time $t$ results in the positional offset

$$\Delta \theta_{\text{persp}} = \mu c t^2,$$  

(91)

(dropping the negative sign). As can be seen from the table, the perspective effect is typically some three orders of magnitude greater than the light-time effect (roughly the ratio of the speed of light to the stellar velocity). However, the actual ratio depends on the angle between the stellar motion and the line of sight, so that for example the star with the largest light-time effect in position (HIP 57939) has only the sixth largest perspective effect. The perspective acceleration is fully taken into account in all the propagation formulae presented in this paper, both with and without the light-time effects.

---

As opposed to an apparent superluminal velocity, $v_{\text{app}} > c$, which is physically possible and allowed by Eq. (13), this ratio is not precisely known in an actual case, it may be approximated by the relative error of the measured parallax, $\sigma_\mu / \sigma_\mu$. Since it can be argued that the application of minute light-time effects is meaningless if the result is in any case biased by the observational errors, we conclude that light-time effects should be ignored at least if $\sigma < 10 \sigma_\mu$. 

It is worth noting that the propagation formulae obtained by neglecting light-time effects (i.e. by formally putting $\tau_\lambda = 0$, as in Sect. 5.5 and Appendix [C]) work for any value of the parallax. The parallax only appears in one propagation formula, Eq. (88), and in the partial derivatives $J_{\mu}$, $J_{\nu}$, and $J_{\gamma}$. All these equations involve the parallax as a multiplicative factor, creating no formal or numerical problem if the value happens to be zero or negative. Physically, such a parallax is of course meaningless, but can nevertheless be regarded as a formal parameter of the model. Brown (in van Altena 2013, Ch. 16) gives more general considerations of the use of small, zero, or negative parallaxes in astrophysical applications of astrometric data.
The propagation formulae are based on the uniform rectilinear model of stellar motions, which at some point breaks down due to the (differential) Galactic acceleration. This effect is estimated in Appendix E, where Eq. (E.4) is derived for the positional offset caused by the acceleration in the Galactic plane. This offset is proportional to \( \sin 2\varpi \), where \( \varpi \) is Galactic longitude, and increases quadratically with time. Since the light-time effect in position also increases quadratically, as given by Eq. (6.11), the relative size of the two effects do not change with time and depend only on the position and velocity of the star in question. Comparing the two formulae it is seen that the light-time effect dominates over the Galactic acceleration if

\[
0.36 \times \left( \frac{v_t}{10^3 \text{ km s}^{-1}} \right)^3 > \left( \frac{b}{1 \text{ kpc}} \right)^2 \times |\sin 2\varpi|.
\]

In a rectangular, heliocentric Galactic coordinate system with \( x \) and \( y \) axes directed towards \( \varpi = 0^\circ \) and \( 90^\circ \), respectively, we find \( \sin 2\varpi = 2xy/(x^2 + y^2) = 2xy/b^2 \). For a given transverse velocity \( v_t \), the light-time effect therefore dominates inside an area around the Sun delimited by four hyperbolae, one in each quadrant, as shown in Fig. 5. Since very few Galactic stars have velocities exceeding 300 km s\(^{-1}\), we conclude that the effect of the Galactic acceleration generally dominates beyond a distance of about 100 pc from the Sun.

6.4. Light-time effects and the Galactic acceleration

The propagation formulae are based on the uniform rectilinear model of stellar motions, which at some point breaks down due to the (differential) Galactic acceleration. This effect is estimated in Appendix E, where Eq. (E.4) is derived for the positional offset caused by the acceleration in the Galactic plane. This offset is proportional to \( \sin 2\varpi \), where \( \varpi \) is Galactic longitude, and increases quadratically with time. Since the light-time effect in position also increases quadratically, as given by Eq. (6.11), the relative size of the two effects do not change with time and depend only on the position and velocity of the star in question. Comparing the two formulae it is seen that the light-time effect dominates over the Galactic acceleration if

\[
0.36 \times \left( \frac{v_t}{10^3 \text{ km s}^{-1}} \right)^3 > \left( \frac{b}{1 \text{ kpc}} \right)^2 \times |\sin 2\varpi|.
\]

In a rectangular, heliocentric Galactic coordinate system with \( x \) and \( y \) axes directed towards \( \varpi = 0^\circ \) and \( 90^\circ \), respectively, we find \( \sin 2\varpi = 2xy/(x^2 + y^2) = 2xy/b^2 \). For a given transverse velocity \( v_t \), the light-time effect therefore dominates inside an area around the Sun delimited by four hyperbolae, one in each quadrant, as shown in Fig. 5. Since very few Galactic stars have velocities exceeding 300 km s\(^{-1}\), we conclude that the effect of the Galactic acceleration generally dominates beyond a distance of about 100 pc from the Sun.

6.5. Relation to the work by Stumpff (1985)

The most complete analysis of the astrometric light-time effects prior to the present treatment was the pioneering study by Stumpff (1985). As in the present work, Stumpff carried out his analysis within the framework of the uniform rectilinear model, made an explicit distinction between true and apparent quantities, solved the quadratic light-time equation, and expressed the propagated quantities in terms of functions of the time of observation. However, there are a number of important differences between the two studies, summarized hereafter.

Stumpff (1985) expressed the propagated quantities in terms of the true, not apparent, velocity. Although he derived the transformation from true to apparent velocity equivalent to our Eq. (17), he did not give the inverse relation in Eq. (18). Instead,
The analytical solution of the apparent path equation for uniform rectilinear motion gives the propagated barycentric position at any instance of time. The postulated constancy of the true velocity enables us to find the propagated apparent velocity. Remarkably, all the light-time effects are conveniently parametrized by two factors, which are equal to 1 when light-time is ignored. We obtain explicit formulae for the propagated astrometric parameters both in the case when light-time effects are included and when they are neglected. We also provide the corresponding elements of the Jacobian matrix to be used in the propagation of covariances. Thus, we have derived a complete set of formulae for the rigorous and fully reversible propagation of astrometric data, and their covariances, over arbitrary time intervals.

The effect of the light-time on the astrometric parameters is roughly proportional to $\mu$. Although the light-time effects are generally very small, they are significant for high-velocity stars within a few tens of pc from the Sun, where they exceed the effects of the curvature of their orbits in the Galactic potential.

Distance should be well known to allow meaningful calculation of the light-time effects. Therefore, the epoch propagation including light-time should only be used for stars with reliable parallax distances: we recommend the criterion $\pi > 10\sigma_\pi$. Astrometric parameters of stars with smaller parallaxes should be propagated neglecting light-time. Thus, the presented technique is applicable both to high- and low-accuracy astrometric data provided that the proper mode of epoch transformation is selected.

A simple example: To illustrate the general error propagation technique using the Jacobian, we give below some very simplified formulae. We emphasize that they should not be used for actual calculations, but are only given for illustration. The simplistic formulae for transforming a celestial position \((\alpha, \delta)\) over the epoch difference \(t\) are
\[
\alpha = \alpha_0 + \mu_\alpha t, \quad \delta = \delta_0 + \mu_\delta t.
\]

It is useful to point out that in this equation the proper motion in right ascension does not contain the factor cos\(\delta\). This is not a good physical model of how the stars move on the sky: in general it describes a curved, spiralling motion towards one of the poles, whereas real (unperturbed) stars are expected to move along great-circle arcs. Although the difference with respect to the rigorous model (Sect. 5) is often very small, it becomes significant over long time intervals or for stars near the celestial poles. In this model, the changes in the proper motion components and in the parallax are neglected and the Jacobian matrix for the epoch transformation is then:
\[
J = \begin{pmatrix}
1 & 0 & 0 & t & 0 & 0 \\
0 & 1 & 0 & 0 & t & 0 \\
0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 1
\end{pmatrix}.
\]

The inverse transformation is obtained by reversing the sign of \(t\). It is easily verified that the resulting matrix is indeed the inverse of Eq. (A.7).

The covariance matrix for the six astrometric parameters at epoch \(t\) are obtained from (A.3); this yields in particular for the variances in position:
\[
\begin{align*}
\sigma_\alpha^2 &= \sigma_\alpha^2 + 2\mu_\alpha \sigma_\delta \mu_\alpha + \mu_\alpha^2 \sigma_\mu_\alpha^2, \\
\sigma_\delta^2 &= \sigma_\delta^2 + 2\mu_\alpha \sigma_\delta \mu_\delta + \mu_\delta^2 \sigma_\mu_\delta^2
\end{align*}
\]
(with all quantities in the right members referring to the initial epoch). Here the notation \(\rho_{ij}\) means the coefficient of correlation between the astrometric parameters \(x\) and \(y\).

Finally, let us consider an extreme case of very large epoch difference. Putting formally \(t \rightarrow \infty\), we find that
\[
\sigma_\alpha \rightarrow t\sigma_\mu_\alpha, \quad \sigma_\delta \rightarrow t\sigma_\mu_\delta,
\]
while \(\sigma_\mu_\alpha, \sigma_\mu_\delta, \sigma_\mu_\alpha, \sigma_\mu_\delta\) are unchanged. Similarly, after direct calculations, we obtain the limiting forms of all nine correlation coefficients affected by the transformation:
\[
\begin{align*}
\rho^\alpha_\beta &\rightarrow \rho^\mu_\alpha^\mu_\alpha, \quad \rho^\delta_\beta \rightarrow \rho^\mu_\delta^\mu_\delta, \\
\rho^\alpha_\beta &\rightarrow \rho^\mu_\alpha^\mu_\delta, \quad \rho^\delta_\beta \rightarrow \rho^\mu_\delta^\mu_\alpha.
\end{align*}
\]

Although the terms in the right-hand sides of Eqs. (A.9) and (A.10) refer to the initial epoch, we do not show it explicitly because these quantities remain unchanged.

Thus all information about initial covariances of the positions becomes less significant as the epoch difference increases and vanishes in the long run. Similar arguments hold for the rigorous propagation, except that they cannot be demonstrated so easily.
The quantities $X$, $Y$, and $Z$ are defined by the Eqs. (75), (64) and (65). We give below, for reference, these quantities explicitly:

$$X = \sigma_0 \alpha + 2 \tau_{\alpha},$$

$$Y = \sigma_0 \delta + \tau_{\alpha} (1 + Z - \mu_0 \alpha),$$

$$Z = \sqrt{1 + (1 + 2 \tau_{\alpha} / \sigma_0) \mu_0^2 \alpha + (2 + \mu_0 \alpha) \mu_0 \delta}.$$
Appendix C: Elements of the Jacobian matrix neglecting light-time effects

This appendix gives explicit formulae for the 36 partial derivatives constituting the Jacobian matrix of the propagated astrometric parameters for the case when light-time effects are not taken into account. The following formulae can be obtained either by a direct differentiation of the corresponding equations in Sect. 5 or more easily by putting \( f_T = f_V = 1 \) and \( \tau_A = 0 \) in the derivatives in Appendix B. The elements given below are equivalent to the elements given in Vol. 1, Sect. 1.5.5 of the Hipparcos and Tycho catalogues [ESA 1997]. In that publication, the radial proper motion \( \mu_r \) is denoted \( \zeta \), and the distance factor \( f_0 \) is denoted \( f \).

\[

\]

\[
J_{56} = \frac{\partial \mu_0}{\partial \mu_0} = q' [\mu_0 f_0 - 3 \mu (1 + \mu_0 t_f)] f_0 f_D^2 f_V + \mu_\chi + q' \psi_{\mu}
\]
Appendix D: Approximate formulae for the light-time effects

In this appendix we derive approximate formulae for the effects of the light-time on the propagated astrometric parameters. These formulae should not be used for the actual propagation, but only to estimate the significance of the effects.

It is clear from Sect. 5.7 that the light-time effects are determined by the scaling factors in time and velocity, \( f_T \) and \( f_V \). Since these factors are very close to unity, it is useful to introduce two small quantities, \( \varepsilon_T \) and \( \varepsilon_V \), which can be regarded as small parameters of the employed formalism:

\[
f_T = 1 + \varepsilon_T \quad \text{and} \quad f_V = 1 + \varepsilon_V.
\] (D.1)

Since \( \varepsilon_T \) and \( \varepsilon_V \) are zero at \( t = 0 \), it is convenient to represent them as an explicit functions of time. Expanding Eqs. (54) and (57) in a Taylor series in time and keeping the first-order terms, we find that

\[
\varepsilon_T = -\frac{\mu_0^2 \tau \lambda}{2\sigma_0} t \quad \text{and} \quad \varepsilon_V = \frac{\mu_0^2 \tau \lambda}{\sigma_0} t,
\] (D.2)

i.e., \( \varepsilon_V = 2\varepsilon_T \).

As the next step, we express the propagated astrometric parameters as linear functions of \( \varepsilon_T \) and \( \varepsilon_V \) by a series expansion to the first order. We denote the approximate quantities calculated neglecting the light-time effects, that is for \( \varepsilon_T = \varepsilon_V = 0 \), with a tilde. Substituting \( f_T \) from Eq. (D.1) to the definition of the distance factor (43), we get

\[
f_D = \tilde{f}_D - \tilde{f}_D \tilde{\mu} \varepsilon_T t.
\] (D.3)

It follows from Eq. (44) that the propagated barycentric position can be written as

\[
u = \tilde{u} + \tilde{\mu} \tilde{f}_D^2 \varepsilon_T t
\] (D.4)

and formula (43) gives the propagated parallax

\[
\alpha = \tilde{\alpha} - \tilde{\alpha} \tilde{\mu} \varepsilon_T t.
\] (D.5)

Expansion of the product \( \tilde{f}_D^2 \tilde{f}_V \), which appears in the formula of the propagated proper motion (50), to the first order in \( \varepsilon_T \) and \( \varepsilon_V \) gives \( \tilde{f}_D^2 \tilde{f}_V = \tilde{f}_D^2 \tilde{f}_V + \tilde{f}_D^2 \tilde{f}_V \). Since \( \varepsilon_T \) and \( \varepsilon_V \) are of the same order of magnitude, \( \tilde{f}_D \approx 1 \) and \( \tilde{\mu}, t \ll 1 \), we can omit the second term to get

\[
\tilde{f}_D^2 \tilde{f}_V = \tilde{f}_D^2 + \tilde{f}_D^2 \varepsilon_V \quad \text{and} \quad \tilde{f}_D^2 \tilde{f}_V = \tilde{f}_D^2 + \tilde{f}_D^2 \varepsilon_V.
\] (D.6)

The propagated proper motions then become

\[
\mu = \tilde{\mu} + \tilde{\mu} \tilde{f}_D^2 \varepsilon_V,
\] (D.7)

\[
\mu = \tilde{\mu} = \tilde{\mu} + \tilde{\mu} \tilde{f}_D^2 \varepsilon_V.
\] (D.8)

Putting \( \tilde{f}_D = 1 \) in Eqs. (D.4), (D.5), (D.7), and (D.8), we readily obtain the effects of the light-time on the astrometric parameters

\[
\Delta \theta = \frac{\mu_0^2 \tau \lambda}{2\sigma} \quad \text{and} \quad \Delta \sigma = \frac{\mu_0^2 \tau \lambda}{\sigma_0} \tilde{\mu} \varepsilon_T t,
\] (D.9)

\[
\Delta \mu = \frac{\mu_0^2 \tau \lambda t}{\sigma} \quad \text{and} \quad \Delta \mu = \frac{\mu_0^2 \tau \lambda}{\sigma_0} \tilde{\mu} \varepsilon_T t.
\]

We note the following relations between the effects

\[
\Delta \alpha = \frac{1}{2} \mu_0 \mu_0 \Delta \mu \quad \text{and} \quad \Delta \sigma = \frac{1}{2} \Delta \mu.
\] (D.10)
It is instructive to express the effects in terms of the physical parameters, including the effects in velocity:

$$\Delta \theta = \frac{1}{2} \frac{v_t}{c} \left( \frac{v_b}{b} \right)^2 t^2, \quad \Delta \varpi = \frac{1}{2} A \frac{v_t}{c} \left( \frac{v_b}{b} \right)^2 t^2,$$

$$\Delta \mu = \frac{v_t}{c} \left( \frac{v_b}{b} \right)^2 t, \quad \Delta \mu_t = \frac{v_t}{c} \left( \frac{v_b}{b} \right)^2 t, \quad \Delta \nu = \frac{v_t}{c} \left( \frac{v_b}{b} \right)^2 t. \quad (D.11)$$

These relations lead to important conclusions about the behaviour of the effects. The effects on the position and parallax are quadratic functions of time, while the effects on the proper motion and velocity increases linearly with time. This confirms the conclusion drawn from the numerical calculations shown in Fig. 2. All the effects are roughly proportional to the third power of the space velocity, while the dependence on distance is different for the velocities ($b^{-1}$), position and proper motions ($b^{-2}$), and parallax ($b^{-1}$).

For the practical estimation of the effects we give the following formulae for the position,

$$\Delta \theta = \left(0.36 \, \mu \text{as} \right) \times \frac{v_t}{\left(10^3 \, \text{km s}^{-1}\right)^3} \times \frac{b}{\left(1 \, \text{kpc}\right)^2} \times \left(\frac{t}{100 \, \text{yr}}\right)^2,$$

and velocity,

$$\Delta \varpi = \left(0.34 \, \text{m s}^{-1}\right) \times \frac{v}{\left(10^3 \, \text{km s}^{-1}\right)} \times \frac{v_t}{\left(10^3 \, \text{km s}^{-1}\right)} \times \left(\frac{b}{1 \, \text{kpc}}\right)^{-1} \times \left(\frac{t}{100 \, \text{yr}}\right).$$

**Appendix E: Applicability of the uniform rectilinear model**

In this appendix we briefly consider the conditions under which stellar motion may be regarded as uniform. A uniform motion implies absence of acceleration. In practice, however, accelerated motion may be treated as uniform if observable effects of the acceleration are negligible compared to the required astrometric accuracy. The effect of a constant acceleration $a$ on the barycentric position of a star during a timespan $t$ is $\Delta \theta \approx a t^2/2$. The corresponding change in the angular position $\theta$ of the star is $\Delta \theta_\theta = a_t t^2/(2b^2)$, where $a_t$ is the tangential component of the acceleration. The motion may be regarded as uniform if $|\Delta \theta| \ll \sigma_\theta$, the required astrometric accuracy in angular position after time $t$. For the proper motion, we similarly have the condition $|\Delta \mu| \ll \sigma_\mu$, where $\Delta \mu = a_{\mu t}/b$. The former (positional) criterion is usually stricter since $t$ is typically much greater than $2\sigma_\theta/\sigma_\mu$.

The acceleration along the line of sight, $a_b$ (taken to be positive when directed away from the SSB), causes a change in parallax by $\Delta \varpi = -a_b t^2/(2b^2)$, where $A$ is the astronomical unit, and in radial velocity by $\Delta v_r = a_t$. If $a_{\mu}$ and $a_b$ are of similar magnitudes, we find that $|\Delta \varpi|$ is smaller than $|\Delta \theta|$ by a factor $A/b \ll 1$, so the effect in parallax is never a limitation. On the other hand, under fairly realistic assumptions it may happen that the acceleration effect is more important in radial velocity than in position.

We do not consider here the acceleration caused by stellar or planetary companions, which affects specific objects in a very specific way and may be very important. Indeed, as emphasized in the introduction, one of the objectives of the uniform rectilinear hypothesis is precisely to enable the detection of such cases. Rather, we need to consider accelerations that affect all, or most of, the stars and which could therefore potentially render the model invalid as a general basis for high-precision astrometric analyses. The most important such acceleration is caused by the large-scale gravitational field of the Galaxy, i.e. the curvature of Galactic stellar orbits.

At the arbitrary point $b$ in the Galaxy (relative to the SSB) the acceleration vector can be estimated as $a = -\nabla \psi$, where $\psi$ is some suitable model of the Galactic potential (Binney & Tremaine 2008). It should be recalled that the uniform rectilinear model refers to the motion of stars relative to the SSB, and that the SSB itself is subject to some acceleration $a(0)$. The observable effects must therefore be evaluated for the differential acceleration $\Delta a = a(b) - a(0)$, and the quantities $a_\mu$ and $a_t$ discussed above are therefore the components of $\Delta a$ along and perpendicular to the line of sight. In a smooth potential both components vanish as $b \to 0$.

Rather than using a (rather uncertain) global potential model, however, it is more illuminating to analyse the differential effects based on a few relatively well-determined structural Galactic parameters. We assume an axisymmetric potential in galactocentric cylindrical coordinates $(R, z)$ and consider separately the acceleration components in the Galactic plane (along $R$) and perpendicular to it (along $z$). To avoid confusion with the $b$ denoting a star’s distance from the SSB, we subsequently use $\Omega$ to denote Galactic latitude, and $\varpi$ for the longitude.

**Acceleration in the Galactic plane** In the axisymmetric approximation the acceleration in the Galactic plane is directed towards the Galactic centre and of magnitude $a = V(R)/R^2$, where $V(R)$ denotes the circular velocity as radial distance $R$. The Sun is currently located close to the Galactic plane at a radius $R_0 = 8.4$ kpc from the Galactic centre, where the circular velocity is $V_0 \equiv V(R_0) = 254$ km s$^{-1}$ (Reid et al. 2009). The expected acceleration at the location of the Sun is therefore $a_\| \equiv V_0^2/R_0^2 \approx 2.5 \times 10^{-10}$ m s$^{-2}$.

The effects in position and proper motion are proportional to $a_{\mu}/b$, which in a smooth potential become distance-independent for sufficiently small $b$, that is in the solar neighbourhood. It is interesting to derive the corresponding local approximations for the acceleration components. This can be done in complete analogy with the well-known derivation of the Oort formulae for the radial and tangential velocities of circular motions in terms of the Oort constants $A$ and $B$ (e.g. Binney & Merrifield 1998). With $a(R)$ denoting the acceleration towards the Galactic centre at radius $R$, we find

$$a_{\mu}/b = -E \sin \sqrt{2} \psi, \quad a_t/b = F + E \cos \sqrt{2} \psi,$$

(E.1)

where $\psi$ is the Galactic longitude of the star, as seen from the Sun, and

$$E = \frac{1}{2} \left( \frac{a_0}{R_0} - \frac{da}{dR|_{R=R_0}} \right), \quad F = -\frac{1}{2} \frac{a_0}{R_0} - \frac{da}{dR|_{R=R_0}} \quad (E.2)$$

The acceleration of the SSB causes some observable effects on the proper motions of all objects due to the slowly changing secular aberration (Bastian et al. 2005). Studies of Galactic motions should in principle be made in a galactocentric reference system, and the transformation from barycentric quantities needs to take this effect into account as well as the secular aberration itself (for the positions). This is not further discussed here.
are constants analogous to $A$ and $B$ in the Oort formulae. Using
\( a(R) = V(R)/R^2 \) we can in fact express $E$ and $F$ in terms of the
Oort constants as
\[
E = 2A(A - B), \quad F = (A + B)(A - B).
\] (E.3)

In Eq. (E.1) we take $a_\perp$ to be positive in the direction of increasing $\nu$. Since the Galactic rotation curve is nearly flat ($A + B = 0$),
we have $F \approx 0$ and $E \approx \Omega_0^2$, where $\Omega_0 = V_0/R_0 = 9.8 \times 10^{-16}$ s$^{-1}$
is the circular angular velocity at the Sun. In the solar neighbourhood,
the effect of the curvature of Galactic orbits on the position
after time $t$ can therefore be estimated as
\[
\Delta \theta = -\frac{1}{2} (\Omega_0^2) \sin 2\nu \approx (-1.0 \text{ mas}) \times \left( \frac{t}{\text{100 yr}} \right)^2 \sin 2\nu, \quad (E.4)
\]
thus negligible at the $1 \text{ mas}$ precision for time intervals up to
100 yr. The corresponding effect on the radial velocity is
\[
\Delta v_r = \Omega_0^2 b \cos 2\nu \\
\approx (0.09 \text{ m s}^{-1}) \times \left( \frac{t}{\text{100 yr}} \right) \times \left( \frac{b}{1 \text{ kpc}} \right) \cos 2\nu, \quad (E.5)
\]
where we have again assumed a flat rotation curve.

Beyond the solar neighbourhood, e.g. at distances of the order of $R_0$ from the Sun, the differential acceleration is of the
order of the solar acceleration, or $a_0 = \Omega_0^2 R_0$. The astrometric
effects, being proportional to $a_\perp/b \sim a_0/R_0 = \Omega_0^2$, are therefore of
the same order of magnitude as computed above for the solar
neighbourhood.

**Acceleration perpendicular to the Galactic plane**  In the solar
neighbourhood, the component of the acceleration perpendicular
to the Galactic plane, at distance $z$ above the plane, is approxi-
mately given by $a(z) = -2\pi G \Sigma(z)$, where $\Sigma(z) = \int_z^{\infty} \rho(z') \, dz'$
is the surface density within $z$ of the Galactic plane. Within a few
hundred pc from the Sun we can assume an approximately con-
stant mass density $\rho_0$, yielding $a(z) = -Kz$ where $K = 4\pi G \rho_0$ is
the square of the angular frequency of the oscillations in $z$. The
acceleration relative to the SSB follows the same formula if $z$ is
interpreted as the vertical coordinate of the star relative to the
Sun, that is, $z = b \sin \beta$. For the components of $a(z)$ perpendicular
to and along the line of sight we readily find
\[
a_\perp = -\frac{1}{2} K \sin 2\beta, \quad a_0/b = -\frac{1}{2} K + \frac{1}{2} K \cos 2\beta, \quad (E.6)
\]
where $a_\perp$ is positive in the direction of increasing $\beta$. Using
\( \rho_0 = 0.1 M_\odot \text{ pc}^{-3} \) (Holmberg & Flynn 2000), we have $K \approx
5.7 \times 10^{-30}$ s$^{-2}$, and the accumulated effects in position and radial
velocity after time $t$ can then be estimated as
\[
\Delta \theta = -\frac{1}{4} Kt^2 \sin 2\beta \approx (-2.9 \text{ mas}) \times \left( \frac{t}{\text{100 yr}} \right)^2 \sin 2\beta, \quad (E.7)
\]
and
\[
\Delta v_r \approx -K t b \sin^2 \beta \\
\approx (-0.28 \text{ m s}^{-1}) \times \left( \frac{t}{\text{100 yr}} \right) \times \left( \frac{b}{1 \text{ kpc}} \right) \sin^2 \beta. \quad (E.8)
\]
These approximations are valid for distances $b$ up to a few hundred
pc, beyond which the effects may be considerably smaller.

The effects of the acceleration perpendicular to the Galac-
tic plane are therefore more important than the radial accelera-
tion, which simply reflects the shorter oscillation period in the
