KEY WORDS: Climate Change, Landscape Responses, Köppen-Geiger Climate Classification, China

ABSTRACT:

Under the background of global warming, China with diverse climate types is experiencing dramatic climate change. In this study, we produced a series of climate type map of China at 0.1° resolution from 1979 to 2018 using Köppen-Geiger climate classification, which provided continuous fine-scale decadal climate classification data for climate researches in China. Based on these climate maps, we divided China into four main climate zones: arid climate zone located on the north of Tibetan Plateau and west of Inner Mongolian Plateau, temperate climate zones in southern China, cold climate zone occupied most of Northeast Plain and North China Plain, and polar climate zone on Tibetan Plateau. The distribution of main climate classes in China have not changed significantly over 40 years, while the climate change mainly occurs at the levels of climate type and subtype changes. The frequency of climate changes shows the climate sensitivity of the region, and we identified the transition areas of climate zones with a high sensitivity to climate change. The change of climate types shows an obvious trend of rising temperature in all climate zones of China and increasing precipitation in most climate zones of China (the cold climate zone shows no significant dry or wet change). Overall, the climate in China is generally getting warmer and wetter in the past 40 years. Furthermore, we analysed the landscape responses on climate change with land cover data, e.g. the vegetation type variations in southern China and the snow cover fluctuations on Tibetan Plateau.

1. INTRODUCTION

China is located at the east of Asia and west of the Pacific. It covers 9.6 million km² area with over 18000 km mainland coastline, including a large area of mountains and plateaus. China ranges from 70°E to 140°E and from 15°N to 55°N, spanning tropical, subtropical, warm temperate, temperate and cold temperate zones. The vast land forms a great variety of climates.

Climate variability is not only reflected in spatial differentiation. It also keeps changing over time. Evidence shows that the global climate is changing rapidly these days. Recent climate changes have had widespread impacts on human and natural systems. It exposes people, societies, economic sectors and ecosystems to risk (IPCC, 2014). Yet climate change in China is even more dramatic than global climate change. Wang and Gong (2000) pointed out that the rate of warming (0.3°C/10a) over China has been considerably greater than the global warming of 0.19°C/10a in the last two decades of the 20th century. Therefore, the study of the climate change in China is of great significance to whether mitigate the climate change or adapt to it.

Köppen classification (Köppen, 1931) is a widely accepted system of climate classification. It uses natural vegetation as an expression of climate, takes monthly average air temperature and precipitation as the classification indicators to characterize temperature, precipitation and seasonality. The schemes set strict criteria to recognize the world climate as five main climate classes and 13 climate type. Although there are some criticisms of static division of climate classes (Triantafyllou, & Tsonis, 1994), the rigid standards facilitate quick and easy access to climate classification of clear boundaries. These advantages make it a broad applied value, especially to detect recent climate changes in global, regional and country scales (Baker et al., 2010; Fraedrich et al., 2001; Wang, & Overland, 2005; Zhu, & Li, 2015). Thus, we intend to use Köppen classification to study the climate change in China.

Climate data are mostly based on either station measurements or gridded datasets. Station measurements are accurate and reliable, but the data acquisition is limited by the distribution of meteorological stations and the valid observation period. In China, especially on the Tibetan plateau, there is quite sparse station density on the vast plateau and mountainous area. It cannot provide sufficient valid observation data. Therefore, gridded datasets are more commonly used in large-scale climate studies, for example, Climate Research Unit (CRU) gridded data at a 2.5° resolution (Kalvova et al., 2003) and 0.5° resolution (Fraedrich et al., 2001), China monthly surface air temperature and precipitation 0.5°×0.5° gridded dataset (Zhu, & Li, 2015). However, these resolutions are a little bit coarse and any sub-grid resolution climate variability will be ignored. Thus, a finer scale study on climate classification is needed. Then Peet et al (2007) interpolated the whole period of station record onto a 0.1° × 0.1° grid and made one high-resolution global map of Köppen climate classification to reflect long-term world climate. This updated climate map is widely accepted in the field of climate change. But unfortunately, only one phase of climate classification is not enough for time series analysis to detect the climate change.

In this study, we would like to select a long-term high-resolution meteorological dataset to produce a series of finer-scale climate classification map for climate dynamic studies. Furthermore, we will discuss the land cover changes in different climate zones to disclose the landscape responses on climate change.
tropical, C for temperate, D for cold, E for polar and B for arid. Identifies five main climate classes using letters A to E, A for (Peel, Finlayson, & McMahon, 2007) to determine the classes are further subdivided by the seasonality of temperature one is generated from the dry condition. Then these climate First four of them are based on the thermic zones and the last (Table 1). We used the SAGA software for climate classification (Conrad et al., 2015).

We used the modified Köppen-Geiger climate classification (Köppen, 1948) and precipitation to 13 climate types and 31 climate subtypes. We used the modified Köppen-Geiger climate classification (Conrad et al., 2015).

We used the China Meteorological Forcing Dataset (CMFD), a high spatial-temporal resolution gridded near-surface meteorological dataset, which was made through fusion of remote sensing products, reanalysis dataset and in-situ observation data at weather stations. Data were recorded from January 1979 to December 2018 with a temporal resolution of three hours and a spatial resolution of 0.1° (Yang, & He, 2018). We pre-processed the 2m air temperature and precipitation rate data provided by CMFD and made the statistical calculation to obtain monthly average air temperature and precipitation.

2.1 Meteorological Dataset

We used the China Meteorological Forcing Dataset (CMFD), a high spatial-temporal resolution gridded near-surface meteorological dataset, which was made through fusion of remote sensing products, reanalysis dataset and in-situ observation data at weather stations. Data were recorded from January 1979 to December 2018 with a temporal resolution of three hours and a spatial resolution of 0.1° (Yang, & He, 2018). We pre-processed the 2m air temperature and precipitation rate data provided by CMFD and made the statistical calculation to obtain monthly average air temperature and precipitation.

2.2 Köppen-Geiger Climate Classification

We used the modified Köppen-Geiger climate classification (Peel, Finlayson, & Memehall, 2007) to determine the distribution of climatic type. This modified classification identifies five main climate classes using letters A to E, A for tropical, C for temperate, D for cold, E for polar and B for arid. First four of them are based on the thermic zones and the last one is generated from the dry condition. Then these climate classes are further subdivided by the seasonality of temperature and precipitation to 13 climate types and 31 climate subtypes (Table 1). We used the SAGA software for climate classification (Conrad et al., 2015).

2.3 Landscape Responses

To explore the landscape responses to climate change, we combined the land cover changes with the change of climate zones. The time series of land cover changes were derived by the MODIS Combined Terra and Aqua Land Cover Type Yearly L3 Global 0.05Deg Climate Modelling Grid (CMG) (short name: MCD12Q1) (Friedl, & Sulla-Menashe, 2015). The International Geosphere Biosphere Programme (IGBP) global vegetation classification scheme is used in this study, which identifies 17 land cover classes including 11 natural vegetation classes, 3 developed and mosaicked land classes, and 3 non-vegetated land classes.

For the polar climate zones on the Tibetan plateau, snow cover is a strong indicator of climate change (Cess, et al., 1991). MODIS/Terra Snow Cover 8-Day L3 Global 500m SIN Grid (short name: MOD10A2) reports the maximum snow cover extent during an eight-day period in 500m resolution (Hall, & Riggs., 2016). We used MOD10A2 data set to calculate the maximum snow cover in the coldest and hottest months of each year to reflect the annual snow cover changes.

To explore the landscape responses on climate change, we calculated the land cover changes on the regional scales and fitted the land cover changes with climate type changes to analyse the relationship between them and reveal the impact of climate change on the landscape.
The map of Köppen-Geiger climate type for China in time series (Fig. 1) shows that all five main climate classes are present in China. The distribution of main climate classes remains stable and the dominant climate class by area is the arid B (29.4%), followed by cold D (26.8%), temperate C (24.0%), polar E (19.5%) and tropical A (0.2%) (Table 2).

The tropical (A) climate only covers a small area, mostly in Hainan Island, and it changes little in the past 40 years. Most part of China are occupied by B, C, D & E climate classes, particularly six main climate types, desert BW, steppe BS, temperate with dry winter Cw, temperate without dry season Cf, cold with dry winter Dw and tundra ET.

The maps depict that China can be roughly divided into four climate zones: Tibetan Plateau (Region I) is mainly covered by the polar (E) climate; the southern China (Region II) which is located on the east of Tibetan Plateau and south of Qinling Mountain and Huaihe River is in the coverage of temperate (C) climate; the region on the north of Tibetan Plateau and west of Inner Mongolian Plateau and north of Qinling Mountain and Huaihe River (Region IV) (Fig. 2).

Region I has a polar climate, mainly the tundra (ET) climate. But in the past 40 years, there is a reduction in ET climate by
-5.7×10^4 km^2/10a, which is accompanied by an upward trend of temperature rise and precipitation increase, and most of the area varying with little overall trend in past 40 years. The only climate change happens at the Junggar Basin in the northwest of China. In the 1980s, Junggar Basin was under the coverage of BWk climate (Fig. 1(a)) which was gradually replaced by the cold steppe (BSk) climate in the next few decades (Fig. 1(b)-(d)). At the same period, the cold climate (Df and Dw) is also increasing slightly in this area. Until now, Junggar Basin is basically occupied by BSk climate (Fig. 1(d)). Although it is still under the arid climate, it has more precipitation now than in the 1980s.

As for Region IV, there are three subtypes (a, b, c) of cold climate with dry winter (Dw) and cold steppe (BSk) climate (Fig. 1). The BSk climate has a relatively constant coverage (15%) from 1979 to 2018. But in the areas covered by Dw climate, the increase in the coverage of Dwa climate was accompanied by the decreases in the coverage of both the Dbw and Dwc climate, which indicated the warming trend of the whole region.

According to the decadal change of Köppen-Geiger climate type map of China, although the distribution of main climate classes in China have not changed significantly in the past 40 years, the climate types in each climate zone have been changing among each other. There is an obvious trend of rising temperature in all climate zones of China and increasing precipitation in most climate zones of China (Region III shows no significant dry or wet change). To sum up, the climate in China is generally getting warmer and wetter in the past 40 years.

### 4. DISCUSSION

#### 4.1 Climate change and climate-sensitive regions in China

We compared four climate maps and calculated the frequency of the climate change over 40 years. 65% of the area did not have any changes on the climate types and we called it a stable climate zone. 22% of the area only change the climate type with a trend of -1.3×10^4 km^2/10a from 1979 to 2018. Figure 1 shows that the region with a reduction of Cwb climate is covered by Cwa climate now. In another word, there is a trend from b subtype (warm summer) to a subtype (hot summer). In the climate map (2009-2018), a subtype (hot summer) has occupied 86% area of Region II and shows that the southern China is keeping warming.

In Region III, cold desert (BWk) climate dominates most of the area varying with little overall trend in past 40 years. The only climate change happens at the Junggar Basin in the northwest of China. In the 1980s, Junggar Basin was under the coverage of BWk climate (Fig. 1(a)) which was gradually replaced by the cold steppe (BSk) climate in the next few decades (Fig. 1(b)-(d)). At the same period, the cold climate (Df and Dw) is also increasing slightly in this area. Until now, Junggar Basin is basically occupied by BSk climate (Fig. 1(d)). Although it is still under the arid climate, it has more precipitation now than in the 1980s.

The statistic result also shows some climate-subtype conversion from BWk to BSk climate in the western Tibetan Plateau. These two climate types are two subtype of the arid cold climate which differ in the mean annual precipitation. Although they are both arid climates, BWk climate has even less precipitation than BSk climate does. Therefore, the change from BWk to BSk climate reflects the increasing precipitation on the Tibetan Plateau, which confirms Wu et al.’s conclusion (2015) again that the main trends of climate change on Tibetan Plateau are temperature rise and precipitation increase, and most of the areas was ascending to more humid status.

#### Table 2. Area of each climate type of China in past 40 years

| Climate Type | Area (×98.60 km²) | 1979-1988 | 1989-1998 | 1999-2008 | 2009-2018 |
|--------------|-------------------|-----------|-----------|-----------|-----------|
| A            | 201               | 256       | 282       | 191       |
| Af           | 0                 | 0         | 2         | 3         |

| ET           | 19949             | 19290     | 18270     | 17559     |
| EF           | 252               | 207       | 426       | 370       |
| TOTAL        | 97711             | 97711     | 97711     | 97711     |
humid regions in southern China that we have mentioned in Section 3, the climate-sensitive regions are mainly concentrated around the Hu Line (Heihe-Tengchong) and Qinling Mountain-Huaihe River Line. Hu Line is the boundary between east and west of China, while Qinling Mountain-Huaihe River Line divides China into northern China and southern China. Both of them are located on the transition areas of climate zones and show the high sensitivity to climate change. We need to pay more attention to this region in order to make a timely targeted response to climate change.

4.2 The climate shift at Junggar Basin from desert climate to steppe climate

As a sensitive desert ecosystem, Junggar Basin is highly susceptible to environmental impacts. Its local climate change is affected by the local atmospheric circulation under the background of global warming (Feng et al., 2006). Combined with the unique location in the transitional region between the east Asian monsoon climate and the Mediterranean climate, it becomes an indicator of global climate change (Wei et al., 2003). According to the climate maps, the cold desert (BWk) climate at Junggar Basin was gradually replaced by the cold steppe (BSk) climate in the past 40 years with the rising temperature and increasing precipitation. However, based on the land cover classification results provided by MCD12C1 product, the land cover of Junggar Basin has not changed significantly and is still dominated by barrens. That means the Junggar Basin is still suffering desertification. Despite the rising trend in precipitation, the surface evaporation also grows with the increase of the air temperature. Therefore, the arid climate research like Junggar Basin should integrate more meteorological factor in order to protect the ecological environment of arid areas in the context of global climate change.

4.3 The expansion of temperate climate without dry seasons in southern China and the following vegetation responses

The southern China is dominated by the temperate climate and has gradually converted from Cwa climate to Cfa climate in the past 40 years. The transition from dry winter to no dry season in whole year indicates the general wetter trend. According to the data availability of MCD12C1 product, we calculated the coverage of each kind of land cover in south China from 2001 to 2018 and plotted them as Figure 4.

Combing climate change with local snow cover (Fig. 5), we found that the fluctuation of snow cover area in the coldest month of each year is consistent with the fluctuation trend of ET climate area. The variation range of snow cover area is more dramatic and slightly delayed than the ET climate changes. The snow cover change in the hottest month of each year is relatively flat, but it also shows a consistent trend with ET climate change after data standardization. Through the verification of high correlation between snow cover and ET climate change, we can use the snow cover data to reflect the
climate change on Tibetan Plateau intuitively and make reasonable climate evaluation and prediction. Nowadays, snow
cover data can be easily and quickly obtained by remote
sensing, which is a good support for climate researches, particularly the areas that lack field observation data.

5. CONCLUSIONS

In this study, we produced a series of climate type map of China at 0.1° resolution from 1979 to 2018 using Köppen-
Geiger climate classification, which provided continuous fine-scale decadal climate classification data for climate researches in China. Based on these climate maps, we divided China into four main climate zones: 1) Arid climate (B) zone, located on the north of Tibetan Plateau and west of Inner Mongolia.
Plateau. The main climate types are BWk and BSk. 2) Temperate climate (C) zones in southern China. The main climate types are Cfa, Cwa and Cwb. 3) Cold climate (D) zone, occupied most of Northeast Plain and North China Plain. The main climate types are Dwa, Dwbc and Dwc. 4) Polar climate (E) zone on Tibetan Plateau. The main climate type is ET.

The distribution of main climate classes in China have not changed significantly over 40 years, while the climate change mainly occurs at the levels of climate type and subtype changes. Then we analysed the climate change in two aspects, how often it changed and what kind of climate type conversion happened. On the one hand, the frequency of climate change shows the climate sensitivity of the region. Thus, we identified the transition areas of climate zones with a high sensitivity to climate change. On the other hand, the change of climate types reflects an obvious trend of rising temperature in all climate zones of China and increasing precipitation in most climate zones of China (the cold climate zone shows no significant dry or wet change). Overall, the climate in China is generally getting warmer and wetter in the past 40 years.

Furthermore, we analysed the landscape responses on climate change with land cover data. In southern China, the warm and humid trend of climate change would lead to the increase of forest and decrease of herbaceous and graminoids plants. For the regions with polar climate, snow cover change has a high correlation with the ET climate change, which makes it become an efficient indicator in climate researches. The situation in arid regions is more complicated. The landscape responses on climate change are unclear under the balance between the increase of precipitation and the increase of evaporation caused by the rising temperature. So more meteorological variables need to be introduced to solve this question in the future work.

ACKNOWLEDGEMENTS

This work is funded by the National Natural Science Foundation of China, grant number 41871372. The China Meteorological Forcing Dataset is provided by the National Tibetan Plateau Data Center (https://data.tpdc.ac.cn/). The MODIS Combined Terra and Aqua Land Cover Type Yearly L3 Global 0.05Deg CMG was acquired from the Level-1 and Atmosphere Archive & Distribution System (LAADS) Distributed Active Archive Center (DAAC), located in the Goddard Space Flight Center in Greenbelt, Maryland (https://ladswdb.nascom.nasa.gov/).
