1. ABSTRACT
The James Webb Space Telescope (JWST) will revolutionize our understanding of exoplanets with transit spectroscopy of a wide range of mature planets close to their host stars (<2 AU) and with coronagraphic imaging and spectroscopy of young objects located further out (>10 AU). The census of exoplanets has revealed an enormous variety of planets orbiting stars of all ages and spectral types. With TESS adding to this census with its all-sky survey of the closest, brightest stars, the challenge of the coming decade will be to move from demography to physical characterization. This white paper discusses the wide variety of exoplanet opportunities enabled by JWST’s sensitivity and stability, its high angular resolution, and its suite of powerful instruments. JWST observations will advance our understanding of the atmospheres of young to mature planets and will provide new insights into planet formation.

2. INTRODUCTION
The exoplanet community has made good first steps in characterizing the physical and chemical properties of a small number of planets, but many important questions remain including:

- How does atmospheric composition vary as a function of key exoplanet characteristics, such as mass, radius, level of insolation and location within the planetary system?

- What can we learn about vertical structure of exoplanet atmospheres, cloud formation and global atmospheric motions?

- What can we learn about the formation of exoplanets from, for example, differences in their atmospheric carbon-to-oxygen (C/O) ratios or overall metallicities compared to those of their host stars?

- Do massive planets found on distant orbits (>50 AU) have a different formation mechanism compared to those on closer orbits?

- Can we distinguish between low vs. high initial entropy states for forming massive planets to test two different formation possibilities?

- What are the atmospheric constituents of mini-Neptunes, super-Earths, and even terrestrial planets?

- How does the presence of planets affect the structure of debris disks?

- Do young planetary systems with known massive planets also contain lower mass planets?

JWST is poised to make dramatic advances in all of these areas. The ideas described here are drawn primarily from projects being proposed by the Guaranteed Time Observers (GTO) and the recently selected Early Release Science (ERS) observers. The broader community will come up with many new projects, some of these before launch, but the most important and most innovative uses of JWST will doubtless come after launch as we learn about the telescope and the instruments and more importantly as we learn more about exoplanets themselves.
3. DIRECT IMAGING AND SPECTROSCOPY

3.1 Planet Characterization: JWST’s great strength for direct imaging of planets comes from the stability of its Point Spread Function over a time scale of many hours and its operation in the low background space environment. The smallest Inner Working Angles (IWA) of the NIRCam coronagraphs are relatively coarse, $4\lambda/D$ corresponding to $0.4'' - 0.6''$ at 3.0 and 4.4 $\mu$m. The effective IWA for the MIRI Four Quadrant Phase Masks (4QPMs) is roughly $\lambda/D$, or $0.4''$ at 11.4 $\mu$m. Contrast limits at $1''$ are predicted to approach $10^{-5}$ for NIRCam and $10^{-4}$ for MIRI (Beichman et al 2010). The on-orbit performance of the coronagraphs will depend sensitively on the drift in telescope wavefront error (WFE) over the duration of an observation as well as on the ability of the telescope to hold the star centered on the coronagraphic masks.

The coronagraphs will be used to characterize previously imaged planets across a suite of NIRCam and MIRI filters and to discover new ones as well. From this information, it will be possible to infer a planet’s total luminosity, effective temperature, and thus effective radius, making it possible to estimate its initial entropy which is a direct indicator of its formation mechanism via a “hot” or “cold” start process (Figure 1). JWST’s sensitivity is such that it can detect known young planets at separations of $\leq 1''$ in just a few minutes of integration time. NIRCam’s medium passband filters will be used to characterize exoplanet atmospheres, measuring both the continuum and searching for signatures of CH$_4$, CO and CO$_2$. MIRI’s three 4QPM filters will isolate a band of NH$_3$ expected in cool (<1000 K) objects.

Observations using the NIRSpec slit or IFS (R~ 1,000) and with the MIRI Low and Medium Resolution Spectrometers (LRS, R~100; MRS, R~2500) will yield broad wavelength spectra of more widely separated planets. Some of these targets will be challenging due to the proximity of the host star, e.g. the HR8799 planets. Others will be straightforward due to the faintness of the host star, e.g. 2MASS1207-3239, or to the very wide separation between the planet and host, e.g. HD106906 ($7''$), GU Psc ($42''$) and WD0806-66 ($130''$).

The Aperture Masking Interferometer capability within the NIRISS instrument exploits very high angular resolution (0.5$\lambda/D$) to observe younger, brighter exoplanets located in more distant star forming regions. These include proto-planets – possibly still accreting material – in transition disks such as LkCa15 (Sallum et al 2015).

At separations outside $\sim 1'' - 2''$ NIRCam’s unmatched sensitivity at 5 $\mu$m will reach much lower planet masses than is possible from the ground. Hour-long observations at 4.5 $\mu$m can identify planets with masses below that of Saturn’s mass in previously known planetary systems. Similar searches will be made for $\sim 1 M_{Jup}$ planets within 2–10$''$ radius around 3 of the nearest, brightest debris disk systems. Furthermore, searches of the youngest and closest M stars (often too faint for ground-based adaptive optics imaging) offer the prospect of detecting planets with masses as low as a Uranus mass in orbits as small as 10–20 AU where such planets are thought to form (Schlieder et al 2015).

3.2 Debris Disk and Planets: JWST will open a dramatic new era in the study of debris disks and their interactions with planets. There is a rich literature of models describing the interaction between planets and disks creating multiple rings, gaps, and various asymmetries in our own and other planetary systems (e.g., Wyatt 2006,2008; Ertel et al 2012). The planets responsible for these effects can range in size from Uranus to Jupiter and even down to terrestrial-sized for structures in asteroidal or exo-zodiacal disks (Stark et al 2008) with $\beta$ Pic
4. TRANSITING PLANETS

4.1 JWST Potential for Transit Spectroscopy: JWST has 6.2 times the collecting area of HST and almost exactly 50 times the collecting area of Spitzer. This means that $R \approx 200$ JWST spectra will have comparable S/N to $HST R \approx 35$ near-IR spectra and Spitzer IRAC $R \approx 4.5$ mid-IR photometric observations of equal length. Thus JWST will produce considerably higher resolution and broader wavelength spectra than obtained by HST and will also provide the first high S/N mid-IR emission and transmission spectra of exoplanet atmospheres.

JWST spectra of transiting planets will span numerous molecular features over wavelengths from less than 1 to more than 10 $\mu$m. From the strengths of the common molecules, CH$_4$, CO, CO$_2$, H$_2$O, and NH$_3$ (not yet detected), one can infer a planet’s C/O ratio and overall metal abundance, constraining its formation history (e.g., Brewer et al. 2017). JWST will be able to obtain high quality transmission and emission spectra of numerous warm-to-hot planets down to $\sim 10$ Earth masses or less (Greene et al. 2016; Rocchetto et al. 2016; Molliere et al. 2017), advancing exoplanet characterization into a new era. Figure 2 shows 1.1 – 1.7 $\mu$m H$_2$O absorptions observable by HST as well as longer wavelength 1.7 – 11 $\mu$m features of CH$_4$, CO, CO$_2$, and NH$_3$ that vary with temperature and will be diagnostic of the atmospheric composition and chemistry of cool to hot ($400 \leq T_{eq} \leq 3000$ K) planetary atmospheres.

JWST’s instruments are well suited to transit spectroscopy: a) NIRISS SOSS mode uses a unique grism to produce a slitless spectrum.
spanning 0.6 – 2.8 \( \mu m \) in 2 orders simultaneously with \( R \equiv \lambda/\delta\lambda \simeq 700 \) resolving power; \textit{NIRCam} has Si grisms that produce \( R = 1100 – 1700 \) slitless spectra over 2.4 – 5.0 \( \mu m \) wavelengths. We expect that the \textit{NIRCam} dispersed Hartmann sensor (DHS) will be available for scientific use starting in Cycle 2. This will allow simultaneous 1 – 2 \( \mu m \) and a subset of 2.4 – 5.0 \( \mu m \) spectroscopy (Schlawin et al. 2017); \textit{MIRI LRS} provides a slitless mode that acquires low resolution (\( R \sim 100 \)) spectra over 5 – \( \sim 12 \) \( \mu m \) wavelengths (Kendrew et al. 2015; \textit{NIRSpec} provides a wide, 1.6" \( \times \) 1.6" slit that is intended to minimize slit modulation of spectra in the presence of telescope jitter (Ferruit et al. 2014) and isolates targets from nearby stars. All of the 6 \textit{NIRSpec} gratings and its 0.6 – 5 \( \mu m \) prism can be used for time series transit spectroscopy with this aperture.

**Figure 2.** Equilibrium molecular feature strengths and a simulated \textit{JWST} spectrum of a warm (\( T_{eq} = 960 \) K) sub-Saturn mass planet with a H-dominated, cloud-free atmosphere (HAT-P-12 b system parameters). Model spectra were created using the CHIMERA suite (Line et al. 2013, 2014), and simulated \textit{JWST} observations for 1 transit at each wavelength are shown. \textit{JWST} spectra will probe the transition from CO to CH\(_4 \) dominance in exoplanet atmospheres and will sensitively detect non-equilibrium chemistry (courtesy E. Schlawin).

### 4.2 Archetypal Transiting Systems:

Several studies have simulated \textit{JWST} spectra for a variety of planet types and have assessed what can be learned from these data from direct examination of spectra (Deming et al. 2009; Barstow & Irwin 2016; Molliere et al. 2017; Morley et al. 2017) or statistical Bayesian retrieval techniques (Greene et al. 2016; Barstow et al. 2016; Batalha & Line 2017; Howe et al. 2017).

**Hot Jupiters** with bright host stars will generally have high S/N transmission and emission spectra in a single transit or secondary eclipse. Figure 3 shows that a hot Jupiter like HD 209458 b would have absorption features of several hundred parts per million (ppm) if its atmosphere was cloud-free, and these would be detected at high S/N. Even a cloudy atmosphere (opaque cloud at 1 mbar) would show \( \sim 100 \) ppm features of H\(_2\)O, CO, and CO\(_2\) that would be detected easily.

**Warm Neptune** planets with masses \( M \sim 20 M_\oplus \) and equilibrium temperatures 600 K\(< T_{eq} < 1000 \) K will also be amenable to characterization with \textit{JWST} transmission and emission spectroscopy. Transmission feature strengths can also be several hundred ppm in size for M dwarf host stars, and strong H\(_2\)O and CH\(_4\) features can be detected at high S/N for bright host stars, \( K \leq \sim 7 \) mag. Figure 3 shows that a \( T_{eq} = 700 \) K planet like GJ 436 b will have a detectable emission spectrum at \( \lambda > 4 \mu m \).

**H-dominated mini-Neptune** planets (\( R \simeq 2 R_\oplus \)) with bright M star hosts are also expected to have similarly strong transmission and emission features.

**Super-Earth and Earth-sized** planetary atmospheres will be difficult but not impossible to characterize with \textit{JWST}; numerous transmission or emission spectra will likely need to be co-added to make confident detections of their weak features (Morley et al. 2017). Some TRAPPIST-1 planets will be observed multiple times in transmission with \textit{NIRISS} or \textit{NIRSpec} or in emission with \textit{MIRI} (at \( \lambda > 10 \mu m \)) in an
effort to detect atmospheric features and study their thermal emission.

4.3 Expected Characterization Results: Atmospheric compositions will be constrained with transmission spectra of warm Neptunes to hot Jupiters which have clear atmospheres with solar to $\sim 100 \times$ solar metallicities ($0 \leq [M/H] \leq 2$). Using information retrieval techniques, Greene et al. (2016) show that H$_2$O and CO (the dominant molecular components) can be constrained to factors of 1.5 – 2 with transmission spectra of hot Jupiter planets in favorable systems. The mixing ratios of H$_2$O and CH$_4$, the dominant molecules in cooler atmospheres, can be constrained to a factor of 3 – 10 for warm Neptune and sub-Neptune planets with clear atmospheres.

C/O ratios and metallicity provide clues to a planet’s formation history. In addition to C/O (e.g., Brewer et al. 2017), overall planet metal enrichment $[M/H]$ may also be related to formation scenarios. Gas and ice giant solar system planets have $[M/H]$ values that increase by a factor of $\sim 30$ as their masses decrease from Jupiter to Uranus (Kreidberg et al. 2014). Planet formation scenarios can be investigated by measuring the C/O ratios of exoplanet atmospheres with JWST. Greene et al. (2016) show that JWST spectra will likely be able to constrain C/O ratios to within $\sim 50\%$ for transmission or emission spectra of clear to cloudy hot Jupiters obtained over a single transit or secondary eclipse at all wavelengths 1 – 11 $\mu$m.

3-D thermal profiles, chemical disequilibrium, and cloud properties will also be revealed in JWST spectra. Emission spectra will reveal dayside temperature-pressure profiles over a large pressure range $\sim 1$ bar (e.g., Line et al. 2014), and transmission spectra will measure the temperatures and compositions in planet terminators. Phase curve spectra will also reveal global circulation patterns in these parameters. Chemical disequilibrium due to vertical mixing or photochemistry (e.g., Line & Yung 2013) should also be detectable. Finally, cloud particles will contribute to the mid-IR emission spectra of hot planets (e.g., Crossfield 2015), and cloud-top pressures can be retrieved from transmission spectra (e.g., Greene et al. 2016).

4.4 Characterizing Terrestrial Atmospheres: M dwarf stars will be the most favorable hosts for characterizing Earth-sized planets via transit techniques. Transmission spectroscopy of true Earth analogs (size, temperature, composition) will be exceptionally difficult because of the minuscule signals ($\sim 10$ ppm or less; Schwieterman et al. 2016). However, transmission signals are expected to be larger and potentially detectable for several known warmer Earth-sized planets if they have non-Earth-like atmospheric compositions (Morley et al. 2017). The thermal emission of the $T_{\text{eq}} = 400$ K TRAPPIST-1 b planet is expected to be about 300 ppm relative to its star at wavelengths 10 – 15 $\mu$m. Planned JWST MIRI observations are expected to detect this emission at $S/N \geq 5$ in 5 secondary eclipses in the 12.8 $\mu$m and 15 $\mu$m filters. Detection at 12.8 $\mu$m and non-detection at 15 $\mu$m would indicate a strong Earth-like atmospheric CO$_2$ feature. In principle, dozens of observations could be co-added to search for the $\sim 50$ ppm mid-IR emission signals expected for $T_{\text{eq}} < 300$ K planets (e.g., TRAPPIST-1 d and e). However this requires significantly better performance than JWST requirements and must be verified on-orbit.

5. CONCLUSION

JWST offers dramatic new spectroscopic and coronagraphic capabilities for the study of planets ranging in mass from Earths to Jupiters in orbits from a few days to thousands of years. JWST observations will shift exoplanet science from its census-taking phase into a period of detailed physical characterization. Future missions like LUVOIR, HabEx and OST will some-
Figure 3. LEFT: Clear (blue curve) and cloudy (green curve) chemical equilibrium models of a hot Jupiter planet with solar composition. HD 209458 b system parameters were used. RIGHT: Solar abundance (blue curve) and high mean molecular weight (1000× solar, green curve) emission spectra of a warm Neptune planet in chemical equilibrium. GJ 436 b system parameters were used. BOTH: Simulated JWST NIRISS SOSS, NIRCam grism, and MIRI LRS data are shown as black points and error bars and binned to $R \leq 100$, with one transit or secondary eclipse simulated at each wavelength.
