Do reality distortions contribute to an increased risk of violent offending in schizophrenia? – a narrative review

Aims. To critically examine the factors that drive an increased risk of violence in the schizophrenic population, with emphasis on the role played by reality distorted symptoms.

Background. A multitude of studies have reported a positive association between schizophrenia and violence. Many of the risk factors for violence among the non-mentally disordered population, such as substance use, childhood conduct problems and victimisation, are the same as for persons with schizophrenia. There remains controversy however as to whether reality distorted symptoms themselves contribute to the increased risk of violence.

Method. Relevant literature was identified through a search of the following databases: PubMed, EMBASE, and PsycINFO. Data were appraised and synthesised to provide a comprehensive overview of the current evidence base for the role of reality distorted symptoms in violence in schizophrenia.

Result. Studies ascertaining the contribution of reality distorted symptoms in violent behaviour have produced contradictory results. At a population level, several epidemiological surveys have found little or no contribution for reality distorted symptoms. Such studies frequently show that violence can be accounted for almost entirely by other factors such as substance use and victimisation. However studies investigating relationships between clinical diagnoses and population-wide violence may be unable to detect association at the symptom level. A number of studies have found strong associations between schizophrenia and violence which was not explained by comorbid substance use and have shown strong associations between specific reality distorted symptoms (in particular persecutory delusions accompanied by anger) and violent behaviour.

Conclusion. There is heterogeneity in the relationship between schizophrenia and violence. Factors that are associated with increased risk of violence among the schizophrenic population are also pertinent to those without mental disorders. With regards to the pathways to violence in schizophrenia the following conclusions may be drawn: there is an well-established increased risk of violence associated with schizophrenia which has been replicated in many studies; this risk is driven largely by substance use but other factors such as victimisation are also important; there is evidence that reality distorted symptoms, particularly persecutory symptoms, play a role in violent behaviour in some patients, particularly when co-occurring with anger; finally, there may be shared aetiological links between schizophrenia and antisocial behaviour.

Mindfulness based cognitive therapy for recurrent depressive disorder

Aims. Mindfulness-based therapies have been demonstrated to be effective in reducing anxiety, stress and depressive symptoms in adults. Depression is a chronic relapsing condition. Major depressive disorder is one of the most common causes of ill health and functional impairment.

Our goal was to assess the real world clinical effectiveness of Mindfulness Based Cognitive Therapy (MBCT) for Recurrent Depressive Disorder in three domains:
- Depression, anxiety and stress levels
- Mindfulness level
- Self-compassion level

Method. Patients with a diagnosis of Recurrent Depressive Disorder (primary or secondary diagnosis) were referred by their community mental health team to participate in an 8-week educational MBCT programme. Participants completed the Depression, Anxiety and Stress (DASS), 5-Facet Mindfulness and Self Compassion self-rated scales prior to commencing and at the end of the course. They were also invited to give qualitative feedback at the end of the course.

Data were collected from four groups who completed the course over a period of twelve months. A paired samples test was used to compare pre and post intervention scores to determine effect size.

Result. We had complete data for 19 participants out of a cohort of 34. Pre intervention scores were similar for both groups.

The mean age of the cohort was 47 years (SD of 10 years), 3 male, 16 female.

Patients showed a clinically significant reduction of symptoms in depression, anxiety and stress, with respective reductions of 48%, 26% and 43% post intervention. Results were statistically significant for depression and stress p <0.001 but not for anxiety p = 0.130.

Positive trends were seen in all domains of the 5-Fact Mindfulness and Self Compassions scales, with mean improvements of 28.2% and 35.3% respectively. All results were statistically significant.

We also collected anonymized qualitative feedback which highlighted themes of empowerment, skill acquisition and improved coping.

Conclusion. Numerous studies have demonstrated poor compliance with antidepressant treatments commonly prescribed in Recurrent Depressive Disorder. This small scale study demonstrates a statistical and clinical benefit of MBCT for these patients, supporting greater use of such novel non-pharmacological therapeutic options as treatment strategies.
