ABSTRACT

We report a case of myocarditis in an adult patient with recent coronavirus disease 2019 (COVID-19) infection presenting as recurrent ST-segment elevation, mimicking coronary vasospasm. This case highlights the wide range of presentations of COVID-19–related myocarditis. The novel teaching point is that COVID-19 myocarditis can present with acute manifestations such as chest pain and transient ST-segment elevation even several weeks after complete recovery from the initial infection. Cardiac magnetic resonance imaging should be considered in patients with chest pain syndromes and angiographically normal coronary arteries, as the presence of late gadolinium enhancement and a high T2 signal can be diagnostic. Follow-up cardiac magnetic resonance imaging may be used to assess resolution.

CASE

A 25-year-old man with a history of mild coronavirus disease-2019 (COVID-19) infection, characterized by a low-grade fever and malaise for several days, with complete recovery 6 weeks prior, presented to the emergency room with intermittent episodes of substernal chest pain, with radiation to both arms. He denied diaphoresis and shortness of breath. On initial evaluation, the patient was awake and conversant, with a heart rate of 82 beats per minute, blood pressure of 131/73 mm Hg, a temperature of 36.4°C, and an oxygen saturation of 100% on room air. While in the emergency room, he experienced another episode of similar chest pain.

An electrocardiogram (ECG) performed during the episode demonstrated normal sinus rhythm with 1-mm ST-segment elevations in leads II, III, and aVF, without reciprocal changes (Fig. 1A). Initial laboratory workup was significant for a positive COVID-19 polymerase chain reaction test, elevated high-sensitivity troponin (hs-troponin) level of 10.739 ng/L (normal: < 34 ng/L), and an elevated high-sensitivity C-reactive protein (CRP) level of 27.1 mg/L. A repeat ECG a few minutes after the initial ECG showed normal sinus rhythm with resolution of the ST-segment changes (Fig. 1B).

Etiologies of chest pain with ST-segment elevation and elevated troponin level include ST elevation myocardial infarction (STEMI), myocarditis, perimyocarditis, coronary vasospasm (such as that secondary to illicit drug use), and stress cardiomyopathy. The patient was treated with aspirin at 325 mg, ticagrelor at 180 mg, and intravenous heparin, and he underwent emergent left heart catheterization (LHC), which demonstrated angiographically normal coronary arteries (Video 1, A and B, view video online), with subsequent transfer to the intensive care unit for observation.

**Novel Teaching Points**

- COVID-19 myocarditis can present with acute manifestations, such as chest pain and transient ST-segment elevation, even several weeks after complete recovery from the initial infection.
- CMR imaging should be considered in patients with chest pain syndromes and angiographically normal coronary arteries, as the presence of LGE and a high T2 signal can be diagnostic.
- Follow-up CMR imaging may be used to assess resolution.

Dihydropyridine calcium-channel blocker was started for suspicion of coronary vasospasm.

Further tests, including a urine drug screen, were negative. His hs-troponin levels were serially followed and peaked at 14,122 ng/L without chest pain recurrence. An echocardiogram demonstrated a normal left ventricular ejection fraction of 55%-60%, without wall-motion abnormalities. Within 30 hours, the patient developed another episode of chest pain, with ECG demonstrating recurrent ST-segment elevations in leads II, III, and avF (Fig. 1C). The hs-troponin level rose to 18,235 ng/L. A repeat LHC (Video 1C view video online) was performed along with optical coherence tomography (OCT; Abbott, Abbott Park, IL) and combined near-infrared spectroscopy and intravascular ultrasound (NIRS-IVUS; Abbott, Abbott Park, IL). Both NIRS-IVUS (Fig. 1D; Video 2 view video online) and OCT (Fig. 1E; Video 3 view video online) of right coronary artery showed normal intravascular morphology with minimal lipid burden. Cardiac magnetic resonance (CMR) imaging demonstrated predominantly subepicardial enhancement of the basal to mid inferolateral wall and the apical lateral wall (Fig. 2, A and B), suggestive of myocarditis. The enhancement also included pericardium adjacent to the coronary arteries, as the presence of LGE and a high T2 signal can be diagnostic.

Coronary vasospasm. This case demonstrates the clinical utility of CMR imaging in the diagnosis of myocarditis in the setting of an atypical presentation. The clinical course in this case was mild, and the patient improved with supportive management.

**Discussion**

Cardiac catheterization of COVID-19 patients presenting with ST-segment elevation has shown a variety of findings, ranging from obstructive coronary artery disease to angiographically normal coronary arteries. This is, to our knowledge, the first reported case in the literature of COVID-19 myocarditis presenting late after initial COVID-19 infection with transient and recurrent ST-segment elevation. Our patient was young, without cardiovascular risk factors, and had a history of complete recovery from mild COVID-19 infection 6 weeks prior to presentation. LHC demonstrated normal coronary arteries; OCT and NIRS-IVUS excluded occult plaque/coronary artery dissection and confirmed normal coronary arteries, including the right coronary artery. In this setting, he was referred for CMR imaging for further evaluation of the myocardial injury. Of note, the diagnostic algorithm used in this patient has been used in a published trial that demonstrated the utility of sequential OCT and CMR in patients with myocardial infarction with normal coronary arteries (MINOCA). Parametric imaging (myocardial mapping) is of particular interest in the diagnosis of myocarditis, and elevated T2 values, in addition to T1 parameters, are part of the CMR consensus criteria for nonischemic myocardial inflammation. In our patient, the abnormal T2 signal indicating myocardial edema of the inferolateral wall, and LGE with subendocardial sparing, pointed to acute myocarditis as the underlying mechanism. In absence of other known causes of myocarditis, including vaccination, COVID-19 infection remained the most likely etiology.

Most reported cases of COVID-19 myocarditis describe myocarditis at the time of active infection; however, in our case, the patient presented 6 weeks after recovering from mild COVID-19 infection. The treatment for COVID-19 myocarditis remains uncertain, with options including corticosteroids, interleukin-6 inhibitors, and antivirals. Given his clinical improvement and the lack of data on the use of immunosuppressive therapy, our patient was treated supportively with plans for follow-up CMR imaging as an outpatient. He was additionally advised to restrict physical activity for 3 to 6 months, a recommendation consistent with the American Heart Association/American College of Cardiology scientific statement on myocarditis.

Our findings of residual LGE on follow-up CMR imaging, several months after the acute myocarditis have been previously described in non-COVID-19 myocarditis. Although baseline LGE represents a known predictor of cardiac mortality, the long-term impact of persistent LGE on cardiac events during follow-up remains uncertain. Further study is needed to determine whether COVID-19 myocarditis has similar outcomes, compared with myocarditis from other causes.

**Conclusion**

COVID-19 myocarditis is highly variable in presentation. We report a case of COVID-19 myocarditis developing 6 weeks after initial COVID-19 infection and presenting with transient and recurrent inferior ST-segment elevation, mimicking coronary vasospasm. This case demonstrates the clinical utility of CMR imaging in the diagnosis of myocarditis in the setting of an atypical presentation. The clinical course in this case was mild, and the patient improved with supportive management.
Figure 1. (A) Electrocardiogram (ECG) results demonstrate ST-segment elevation in the II, III, and aVF leads on presentation. (B) Repeat ECG demonstrates resolution of ST-segment elevation. (C) ECG at time of recurrence of chest pain shows ST-segment elevation in the II, III, and aVF leads. (D) Combined near-infrared spectroscopy and intravascular ultrasound demonstrates minimal lipid burden. (E) Optical coherence tomography shows normal right coronary artery.
Figure 2. Cardiac magnetic resonance (CMR) imaging on 1.5T. (A, B) Late gadolinium enhancement imaging in (A) 3-chamber view and (B) short-axis view shows areas of patchy, mid to epicardial enhancement in the basal, mid, and apical lateral and inferolateral wall. (C, D) T2 maps in the short-axis projection show prolonged T2 relaxation times in the anterolateral and lateral wall, consistent with edema. For our clinical reference range, the value of $45 \pm 6$ ms is used for abnormal values consistent with the Society for Cardiovascular Magnetic Resonance recommendation.1 Follow-up cardiac magnetic resonance on 1.5T. (E, F) Late gadolinium enhancement imaging in 3-chamber- and short-axis view shows small interval decrease in late gadolinium enhancement. (G, H) T2 maps in the short-axis projection show resolution of the previously increased T2 signal. For our clinical reference range, the value of $45 \pm 6$ ms is used for abnormal values, consistent with the Society for Cardiovascular Magnetic Resonance recommendation.1
