Chordomas are malignant spinal neoplasms arising from notochordal remnants and most frequently occur in the clivus and sacral spine.\(^1\)\(^-\)\(^3\) Within the mobile spine (C1–L5), chordomas most commonly occur in the cervical and lumbar levels; it is rare for a chordoma to occur in the thoracic spine, especially the upper thoracic spine.\(^4\) Boriani et al. presented 52 consecutive cases of chordomas in the mobile spine over a 50-year period, and only 1 tumor arose from the upper thoracic spine (T4) in an adult patient.\(^5\) In 2012, Fontes and O’Toole reviewed the literature and found only 22 reported cases of thoracic chordomas.\(^4\) Moreover, chordomas usually appear after age 40 years and are rare in young adults and pediatric patients.\(^3\) When chordomas do occur in pediatric patients, they occur almost exclusively along the clivus.\(^6\)

En bloc excision of thoracic chordoma can require an anterior approach, but this strategy usually involves either a standard thoracotomy or a sternotomy. When the tumor invades both chest cavities and the mediastinum, a clamshell thoracotomy can be employed to access all 3 anterior compartments simultaneously. We describe the use of the clamshell thoracotomy to excise a 3-level upper thoracic chordoma. We present the case of a 20-year-old female patient with a 3-level thoracic chordoma that invaded both chest cavities and indented the mediastinum. Because of the upper thoracic spine location and because of the invasion into both chest cavities by the tumor, a formal clamshell thoracotomy was performed to achieve an en bloc excision. The description of the approach presented here includes illustrations and a video.

Methods

**History, Workup, and Surgical Planning**

A 20-year-old otherwise healthy woman presented with shortness of breath and wheezing. Chest radiograph revealed an 8-cm left eccentric mediastinal mass. Standing scoliosis radiographs, cervicothoracic spine CT, and total spine MRI with and without contrast were obtained. An MRI neurogram was also obtained to evaluate possible involvement of the left brachial plexus, but the evaluation results were negative. Imaging revealed an enhancing lesion involving the T2–4 vertebral bodies and expanding predominantly into the left hemithorax, right hemithorax, and mediastinum (Fig. 1). The tumor was indenting the anterior upper mediastinal structures, including the great

Clamshell thoracotomy for en bloc resection of a 3-level thoracic chordoma: technical note and operative video

vessels, esophagus, and trachea, but there was no radiographic evidence of invasion of these structures (Fig. 1D).

The radiographic findings were consistent with a thoracic chordoma. The patient underwent a CT-guided biopsy to establish the diagnosis, which was determined to be chordoma. Because of the atypical presentation in a 20-year-old patient, a repeat CT-guided biopsy was performed, again confirming the diagnosis of chordoma. Once the diagnosis of chordoma was confirmed by pathological analysis, en bloc resection was planned. The invasion into both chest cavities and the mediastinum made removing the chordoma entirely from a posterior-only approach too risky for possible spinal cord damage and intralesional violation. Moreover, the upper thoracic spine poses unique access obstacles not only because of the kyphotic nature of the spine in this area, but also because the mediastinum and the innominate vein are essentially immobile. Thus, a standard median sternotomy would not have sufficed. In addition, because the tumor was in both chest cavities and the mediastinum, a clamshell thoracotomy was planned to access both chest cavities and the mediastinum simultaneously.

Operative Technique

The plan was to first perform posterior stabilization with release of the posterior elements and sacrifice of the involved nerve roots, followed by 3-level en bloc excision from the anterior approach. In the posterior approach, instrumentation was performed from C5 to T8, a T1–5 laminectomy was performed, and T1–2 and T4–5 discectomies were completed. The left-sided T2, T3, and T4 nerve roots were sacrificed to enable en bloc resection during the second stage. In order to release the dorsal spine from the ventral tumor, the entire posterior elements were removed at T2, T3, and T4, including the pedicles, the transverse processes, and the facets. Posterior element resection was correlated with tumor extension by MRI; posterior element excision was carried out until a definite margin between normal bone and tumor was ensured by continual cross referencing the MRI intraoperatively. In addition, the biopsy tract was included and excised during the posterior stage.

Although the patient had consented to a complete clamshell thoracotomy, the second stage was begun with a left-sided hemiclamshell thoracotomy by thoracic surgery to expose the tumor as well as the pericardium and pleural space. Specifically, the surgical saw was used to vertically divide the sternum in the midline, and then to extend the sternotomy laterally at the level of the fifth interspace. Chest wall retractors were placed to expose the upper left hemithorax, and the tumor was identified (Fig. 2). The left lung was found to be free of any significant attachments to the tumor. The left subclavian artery, the innominate and the arch of the aorta were dissected away from the tumor. The posterior parietal pleura was scored circumferentially around the tumor and was dissected toward the midline. Attempts were made to dissect beneath the anterior mediastinum to reach the tumor in the right thoracic cavity; however, adequate exposure and visualization of the right tumor margin could not be achieved because of the mediastinal structures. Therefore, the thoracotomy was extended into a bilateral hemiclamshell thoracotomy to expose the right-sided aspect of the tumor and spine (Fig. 3A and B).

The sternum was divided laterally at the level of the fourth interspace. The right anterior chest wall was then similarly retracted, and complete exposure of the right aspect of the T2 through T4 tumor and vertebral bodies...
was achieved. Once the tumor was completely exposed, the anterior longitudinal ligament and residual annulus at T1–2 and T4–5 was resected to release the T2, T3, and T4 vertebral bodies. The tumor was then dissected off the pleura on the posterior chest wall. After complete dissection laterally, the T2, T3, and T4 vertebral bodies were excised in an en bloc fashion (Fig. 3C and Video 1).

To reconstruct the anterior column, an expandable cage filled with rib autograft was then placed under intraoperative fluoroscopy. The bilateral hemiclamshell thoracotomy was closed by thoracic surgery in the standard fashion. Postoperative radiographs show that the instrumentation was in a good position (Fig. 4A and B). Radiographs of the resected tumor show the vertebral bodies resected with the tumor, verifying en bloc resection (Fig. 4C and D).

Pathological analysis showed a neoplasm invading bone and soft tissues composed of bland epithelioid cells with eosinophilic cytoplasm and occasional cells with cytoplasmic vacuolations, arranged in cords and trabeculae in a background of myxoid matrix. Neoplastic cells were positive for epithelial membrane antigen, S-100, pancytokeratin, and brachyury, consistent with a diagnosis of chordoma. There was a marginal margin against the dura, and the patient was referred for proton beam radiation. Two months after surgery, the patient experienced a 3–4-cm wound breakdown of the incision inferior to the right breast, which was revised by thoracic surgery. The patient was placed on oral antibiotics and recovered well. At the 5-month follow-up, the incision was well healed, motor strength was at least 4+/5 in the arms and legs (assessed over telehealth), and there was residual dysesthesia in the patient’s left arm radiating to her left fifth digit.

**Discussion**

Thoracic chordomas are very uncommon and represent an estimated 1% of all chordomas. Although these tumors tend to arise at a much earlier age than other chordomas, our 20-year-old patient was still well below the mean age of presentation (37.5 years). Early diagnosis of thoracic chordomas is generally difficult because of lack of specific symptoms. The time from onset of symptoms to diagnosis is almost always more than 8 months. MRI is the radiological gold standard for diagnosis and surgical planning. These tumors are isointense to hypointense on T1-weighted MRI, with variable enhancement. On T2-weighted MRI, chordomas are hyperintense but may have some heterogeneity in signal intensity because of calcification and bony sequestration.

En bloc excision of chordomas is currently the most effective way to prevent local recurrence. Although en bloc resection was completed in this case, it is often difficult to achieve en bloc excision without significant morbidity. Moreover, chordomas are considered radioreistant, rendering most radiation therapies ineffective. Chemotherapy is for the most part ineffective. En bloc resection during the initial surgery gives the best chance to achieve long-term local control. According to comprehensive population-based studies, the median overall survival
for chordoma patients is just over 7 years, and the overall 5- and 10-year survival rates are 68%, and 40% respectively.12,13

The clamshell thoracotomy was first described by Kortz in 1958, who used a transverse thoracosternotomy.14 The procedure was further developed and popularized for bilateral lung transplantations by the Washington University group.15,16 Although the midline sternotomy had been previously described for this purpose,17,18 the bilateral clamshell thoracotomy (referred to as a “cross-bow” thoracotomy at the time) was favored because it provided superior access to the left and right pleural spaces, as well as the posterior mediastinum.15,18 Since these initial descriptions, the procedure has been modified to include the unilateral “hemiclamshell” thoracotomy,19,20 as well as the sternum-sparing variant in which a transverse sternotomy is avoided.21 Although the indications and relative advantages of the median sternotomy versus the bilateral clamshell approach for cardiopulmonary transplantation are still debated,22,23 the principal advantage of the bilateral clamshell thoracotomy is superior exposure of both pleural spaces with simultaneous bilateral access to the posterior mediastinum.15,23,24 The clamshell thoracotomy is therefore indicated when wide exposure of these structures is necessary, and it has been used for a variety of purposes, such as repair of cardiac defects25 and treatment of infection,26 pulmonary metastatic lesions,27 traumatic conditions requiring emergent thoracic access,27 and approaches to large intrathoracic tumors.28 In our case, the presence of the tumor in bilateral pleural spaces as well as the need to dissect the tumor away from the posterior mediastinum warranted the bilateral clamshell thoracotomy.

In general, the clamshell thoracotomy is rarely used in spinal surgery; however, there are instances in which the morbidity of this approach is outweighed by the benefit. For instance, Sciubba et al. reported a case of an en bloc resection of a T1–5 ventral chordoma using a 3-staged approach consisting of a posterior approach to instrument the spine, a right-sided thoracotomy to complete the caudal osteotomy, and a left-sided thoracotomy (with interval patient repositioning) to complete the rostral osteotomy and excise the tumor.9 Lau et al. reported the use of unilateral hemiclamshell thoracotomies to excise large spine tumors invading the mediastinum and chest cavity, but they did not report the use of bilateral hemiclamshell thoracotomies.29 The traditional formal clamshell thoracotomy does not involve an upper sternotomy.30 However, because in our patient the sternum was split for the hemiclamshell thoracotomy, the present case is technically a bilateral hemiclamshell thoracotomy (midline sternal split), not a traditional clamshell thoracotomy (no midline sternotomy). Regardless of the nomenclature, the clamshell thoracotomy allowed simultaneous access to both chest cavities and the mediastinum. Figure 5 illustrates the sequence of bony cuts (Fig. 5A), as well as the final thoracic exposure afforded by the bilateral hemiclamshell thoracotomy (Fig. 5B). Although attempts were made to access the entire tumor using a hemiclamshell thoracotomy, the contralateral chest cavity invasion precluded en bloc excision through this approach only. Intraoperative details of the steps of the approach and tumor resection are provided in Video 1.

Although a morbid approach, the bilateral clamshell thoracotomy can be a useful approach in cases which require simultaneous access to both chest cavities for en bloc excision of tumors of the thoracic spine.
