Abstract

We discuss the properties of an ideal relativistic gas of events possessing Bose-Einstein statistics. We find that the mass spectrum of such a system is bounded by $\mu \leq m \leq 2M/\mu_K$, where $\mu$ is the usual chemical potential, $M$ is an intrinsic dimensional scale parameter for the motion of an event in space-time, and $\mu_K$ is an additional mass potential of the ensemble. For the system including both particles and antiparticles, with nonzero chemical potential $\mu$, the mass spectrum is shown to be bounded by $|\mu| \leq m \leq 2M/\mu_K$, and a special type of high-temperature Bose-Einstein condensation can occur. We study this Bose-Einstein condensation, and show that it corresponds to a phase transition from the sector of continuous relativistic mass distributions to a sector in which the boson mass distribution becomes sharp at a definite mass $M/\mu_K$. This phenomenon provides a mechanism for the mass distribution of the particles to be sharp at some definite value.

Key words: special relativity, relativistic Bose-Einstein condensation, mass distribution, mass shell

1 Introduction

There have been a number of papers in the past [1, 2, 3, 4], which discuss the properties of an ideal relativistic Bose gas with nonzero chemical potential $\mu$. Particular attention has been given to the behavior of the Bose-Einstein condensation and the nature of the phase transition in $d$ space dimensions [1, 2]. The basic work was done many years ago by Jüttner [3], Glaser [4], and more recently by Landsberg and Dunning-Davies [5] and Nieto [6]. These works were all done in the framework of the usual on-shell relativistic statistical mechanics.

To describe an ideal Bose gas in the grand canonical ensemble, the usual expression for the number of bosons $N$ in relativistic statistical mechanics is

$$N = V \sum_k n_k = V \sum_k \frac{1}{e^{(E_k - \mu)/T} - 1}, \quad (1.1)$$

where $V$ is the system’s three-volume, $E_k = \sqrt{k^2 + m^2}$ and $T$ is the absolute temperature (we use the system of units in which $\hbar = c = k_B = 1$; we also use the

2
metric $g^{\mu\nu} = (\ldots, +, +, +)$, and one must require that $\mu \leq m$ in order to ensure a positive-definite value for $n_k$, the number of bosons with momentum $k$. Here $N$ is assumed to be a conserved quantity, so that it makes sense to talk of a box of $N$ bosons. This can no longer be true once $T \gtrsim m$ \cite{10}; at such temperatures quantum field theory requires consideration of particle-antiparticle pair production. If $\tilde{N}$ is the number of antiparticles, then $N$ and $\tilde{N}$ by themselves are not conserved but $N - \tilde{N}$ is. Therefore, the high-temperature limit of (1.1) is not relevant in realistic physical systems.

The introduction of antiparticles into the theory in a systematic way was made by Haber and Weldon \cite{11, 12}. They considered an ideal Bose gas with a conserved quantum number (referred to as “charge”) $Q$, which corresponds to a quantum mechanical particle number operator commuting with the Hamiltonian $H$. All thermodynamic quantities may be then obtained from the grand partition function $Tr \{\exp \left[ -(H - \mu Q)/T \right] \}$ considered as a function of $T, V,$ and $\mu$ \cite{12}. The formula for the conserved net charge, which replaces (1.1), reads \cite{10}

$$Q = V \sum_k \left[ \frac{1}{e^{(E_k - \mu)/T} - 1} - \frac{1}{e^{(E_k + \mu)/T} - 1} \right]. \tag{1.2}$$

In such a formulation a boson-antiboson system is described by only one chemical potential $\mu$; the sign of $\mu$ indicates whether particles outnumber antiparticles or vice versa. The requirement that both $n_k$ and $\bar{n}_k$ be positive definite leads to the important relation

$$|\mu| \leq m. \tag{1.3}$$

The sum over $k$ in (1.2) can be replaced by an integral, so that the charge density $\rho \equiv Q/V$ becomes

$$\rho = \frac{1}{2\pi^2} \int_0^\infty k^2 \, dk \left[ \frac{1}{e^{(E_k - \mu)/T} - 1} - (\mu \rightarrow -\mu) \right], \tag{1.4}$$

which is an implicit formula for $\mu$ as a function of $\rho$ and $T$, and in the region $T >> m$ reduces to

$$\rho \approx \frac{\mu T^2}{3}. \tag{1.5}$$

For $T$ above some critical temperature $T_c$, one can always find a $\mu$ ($|\mu| \leq m$) such that (1.4) holds. Below $T_c$ no such $\mu$ can be found, and (1.4) should be interpreted as the charge density of the excited states: $\rho - \rho_0$, where $\rho_0$ is the charge density of the ground state \cite{10} (with $k = 0$; clearly, this state is given with zero weight in

\footnote{In the manifestly covariant theory which we shall use in our study, this charge is naturally associated with particles and antiparticles which are distinguished by the off-shell structure, as in quantum field theory \cite{10}.}

\footnote{The standard recipe according to which all additive thermodynamic quantities are reversed for antiparticles is used.}
the integral (1.4)). The critical temperature \( T_c \) at which Bose-Einstein condensation occurs corresponds to \( \mu = \pm m \) (depending on the sign of \( \rho \)). Thus, one sets \( |\mu| = m \) in (1.4) and obtains, via (1.5) (provided that \( |\rho| \gg m^3 \)),

\[
T_c = \sqrt{\frac{3|\rho|}{m}}.
\]  (1.6)

Below \( T_c \), (1.4) is an equation for \( \rho - \rho_0 \), so that the charge density in the ground state is

\[
\rho_0 = \rho [1 - (T/T_c)^2].
\]  (1.7)

It follows from Eq. (1.6) that any ideal Bose gas will condense at a relativistic temperature \( (T_c \gg m) \), provided that \( |\rho| \gg m^3 \).

Recently an analogous phenomenon has been studied in relativistic quantum field theory [11, 13, 14, 15]. For relativistic fields Bose-Einstein condensation occurs at high temperatures and can be interpreted in terms of a spontaneous symmetry breaking

In this paper we shall use a manifestly covariant form of statistical mechanics which has more general structure than the standard forms of relativistic statistical mechanics, but which reduces to those theories in a certain limit, to be described precisely below. In fact, it is one of the principle aims of this work to provide a mechanism for which this limit can be realized on a statistical level. The results that we obtain are different from those of the standard theories at high temperatures. These theories, which are characterized classically by mass-shell constraints, and the use, in quantum field theory, of fields which are constructed on the basis of on-mass-shell free fields, are associated with the statistical treatment of world lines and hence, considerable coherence (in terms of the macroscopic structure of whole world lines as the elementary objects of the theory) is implied. In nonrelativistic statistical mechanics, the elementary objects of the theory are points. The relativistic analog of this essentially structureless foundation for a statistical theory is the set of points in spacetime, i.e., the so-called events, not the world lines (Currie, Jordan and Sudarshan [16] have discussed the difficulty of constructing a relativistic mechanics on the basis of world lines).

The mass of particles in a mechanical theory of events is necessarily a dynamical variable, since the classical phase space of the relativistic set of events consists of the spacetime and energy-momentum coordinates \( \{ q_i, t_i; p_i, E_i \} \), with no a priori constraint on the relation between the \( p_i \) and the \( E_i \), and hence such theories are “off-shell”. It is well known from the work of Newton and Wigner [17] that on-shell relativistic quantum theories such as those governed by Klein-Gordon or Dirac type equations do not provide local descriptions (the wave functions corresponding to localized particles are spread out); for such theories the notion of ensembles over local initial conditions is difficult to formulate. The off-shell theory that we shall use here is, however, precisely local in both its first and second quantized forms [18, 19].
The phenomenological predictions of on-shell theories, furthermore, provide equations of state which appear to be too rigid. Shuryak [20] has obtained equations of state which are more realistic by taking into account the spectrum of mass as seen in the resonance spectrum of strongly interacting matter. We have shown [21] that Shuryak’s “realistic” equation of state follows in a natural way from the mass distribution functions of the off-shell theory.

We finally remark that the standard formulations of quantum relativistic statistical mechanics, and quantum field theory at finite temperature, lack manifest covariance on a fundamental level. As for nonrelativistic statistical mechanics, the partition function is described by the Hamiltonian, which is not an invariant object, and hence thermodynamic mean values do not have tensor properties. [One could consider the invariant \( p_\mu n^\mu \) in place of the Hamiltonian [22], where \( n^\mu \) is a unit four-vector; this construction (supplemented by a spacelike vector orthogonal to \( n^\mu \)) implies an induced representation for spacetime. The quantity that takes the place of the parameter \( t \) is then \( x_\mu n^\mu \). This construction is closely related to the problem pointed out by Currie, Jordan and Sudarshan [14], for which different world lines are predicted dynamically by the change in the form of the effective Hamiltonian in different frames.] Since the form of such a theory is not constrained by covariance requirements, its dynamical structure and predictions may be different than for a theory which satisfies these requirements. For example, the canonical distribution of Pauli [23] for the free Boltzmann gas has a high temperature limit in which the energy is given by \( 3k_B T \), which does not correspond to any known equipartition rule, but for the corresponding distribution for the manifestly covariant theory, the limit is \( 2k_B T \), corresponding to \( \frac{1}{2} k_B T \) for each of the four relativistic degrees of freedom. For the quantum field theories at finite temperature, the path integral formulation [24] replaces the Hamiltonian in the canonical exponent by the Lagrangian due to the infinite product of factors \( \langle \phi | \pi \rangle \) (transition matrix element of the canonical field and its conjugate required to give a Weyl ordered Hamiltonian its numerical value). However, it is the \( t \) variable which is analytically continued to construct the finite temperature canonical ensemble, completely removing the covariance of the theoretical framework. One may argue that some frame has to be chosen for the statistical theory to be developed, and perhaps even for temperature to have a meaning, but as we have remarked above, the requirement of relativistic covariance has dynamical consequences (note that the model Lagrangians used in the non-covariant formulations are established with the criterion of relativistic covariance in mind), and we argue that the choice of a frame, if necessary for some physical reason, such as the definition and measurement of temperature, should be made in the framework of a manifestly covariant structure.

We consider, in this paper, a relativistic Bose gas within the framework of a manifestly covariant relativistic statistical mechanics [25, 26, 27]. We obtain the expressions for characteristic thermodynamic quantities and show that they coincide
quantitatively, in the narrow mass-width approximation, with those of the relativistic
on-shell theory, except for the value of the average energy (which differs by a factor
$2/3$, as remarked above). We introduce antiparticles and discuss the high temperature
Bose-Einstein condensation in such a particle-antiparticle system. We show that it
corresponds to a phase transition to a high-temperature form of the usual on-shell
relativistic kinetic theory. In the following, we briefly review the manifestly covariant
mechanics and quantum mechanics which forms the basis of our study of relativistic
statistical mechanics.

In the framework of a manifestly covariant relativistic statistical m echanics, the
dynamical evolution of a system of $N$ particles, for the classical case, is governed by
equations of motion that are of the form of Hamilton equations for the motion of $N$
events which generate the space-time trajectories (particle world lines) as functions
of a continuous Poincaré-invariant parameter $\tau$, called the “historical time” [28, 29].
These events are characterized by their positions $q^\mu = (t, \mathbf{q})$ and energy-momenta
$p^\mu = (E, \mathbf{p})$ in an $8N$-dimensional phase-space. For the quantum case, the system
is characterized by the wave function $\psi_\tau(q_1, q_2, \ldots, q_N) \in L^2(\mathbb{R}^{4N})$, with the measure
d$4q_1d4q_2 \cdots d4q_N \equiv d^{4N}q$, ($q_i \equiv q_i^\mu$; $\mu = 0, 1, 2, 3$; $i = 1, 2, \ldots, N$), describing the
distribution of events, which evolves with a generalized Schrödinger equation [29]. The
collection of events (called “concatenation” [30]) along each world line corresponds
to a particle, and hence, the evolution of the state of the $N$-event system describes,
a posteriori, the history in space and time of an $N$-particle system.

For a system of $N$ interacting events (and hence, particles) one takes [29]

$$
K = \sum_i \frac{p_i^\mu p_i^\mu}{2M} + V(q_1, q_2, \ldots, q_N),
$$

(1.8)

where $M$ is a given fixed parameter (an intrinsic property of the particles), with the
dimension of mass, taken to be the same for all the particles of the system. The
Hamilton equations are

$$
\frac{dq_i^\mu}{d\tau} = \frac{\partial K}{\partial p_i^\mu} = \frac{p_i^\mu}{M},
$$

$$
\frac{dp_i^\mu}{d\tau} = -\frac{\partial K}{\partial q_i^\mu} = -\frac{\partial V}{\partial q_i^\mu}.
$$

(1.9)

In the quantum theory, the generalized Schrödinger equation

$$
\frac{i}{\partial \tau} \psi_\tau(q_1, q_2, \ldots, q_N) = K \psi_\tau(q_1, q_2, \ldots, q_N)
$$

(1.10)

describes the evolution of the $N$-body wave function $\psi_\tau(q_1, q_2, \ldots, q_N)$. To illustrate
the meaning of this wave function, consider the case of a single free event. In this
case (1.10) has the formal solution

$$
\psi_\tau(q) = (e^{-iK\tau_0} \psi_0)(q)
$$

(1.11)
for the evolution of the free wave packet. Let us represent $\psi_\tau(q)$ by its Fourier transform, in the energy-momentum space:

$$\psi_\tau(q) = \frac{1}{(2\pi)^2} \int d^4p e^{-i\frac{p^2}{2M}\tau} e^{ip\cdot q}\psi_0(p),$$  \hspace{1cm} (1.12)$$

where $p^2 \equiv p^\mu p_\mu$, $p\cdot q \equiv p^\mu q_\mu$, and $\psi_0(p)$ corresponds to the initial state. Applying the Ehrenfest arguments of stationary phase to obtain the principal contribution to $\psi_\tau(q)$ for a wave packet at $p^\mu_c$, one finds ($p^\mu_c$ is the peak value in the distribution $\psi_0(p)$)

$$q^\mu_c \simeq \frac{p^\mu_c}{M},$$  \hspace{1cm} (1.13)$$

consistent with the classical equations (1.9). Therefore, the central peak of the wave packet moves along the classical trajectory of an event, i.e., the classical world line.

In the case that $p^0_c = E_c < 0$, we see, as in Stueckelberg’s classical example [28], that

$$\frac{dt_c}{d\tau} \simeq \frac{E_c}{M} < 0.$$  \hspace{1cm} (1.14)$$

It has been shown [30] in the analysis of an evolution operator with minimal electromagnetic interaction, of the form

$$K = \frac{(p - eA(q))^2}{2M},$$

that the CPT-conjugate wave function is given by

$$\psi^{CPT}_\tau(t, q) = \psi_\tau(-t, -q),$$  \hspace{1cm} (1.15)$$

with $e \rightarrow -e$. For the free wave packet, one has

$$\psi^{CPT}_\tau(q) = \frac{1}{(2\pi)^2} \int d^4p e^{-i\frac{p^2}{2M}\tau} e^{-ip\cdot q}\psi_0(p).$$

The Ehrenfest motion in this case is

$$q^\mu_c \simeq -\frac{p^\mu_c}{M},$$

if $E_c < 0$, we see that the motion of the event in the CPT-conjugate state is in the positive direction of time, i.e.,

$$\frac{dt_c}{d\tau} \simeq -\frac{E_c}{M} = \frac{|E_c|}{M},$$  \hspace{1cm} (1.16)$$

and one obtains the representation of a positive energy generic event with the opposite sign of charge, i.e., the antiparticle.
It is clear from the form of (1.10) that one can construct relativistic transport theory in a form analogous to that of the nonrelativistic theory; a relativistic Boltzmann equation and its consequences, for example, was studied in ref. [26].

As a simple example of the implications of the classical dynamical equations (1.9), consider the problem of a relativistic particle in a uniform external “gravitational” field, with evolution function

\[
K = \frac{p_\mu p^\mu}{2M} + Mgz
\]

(1.17)

(the external potential breaks the invariance of the evolution function, but that will not affect the illustrative value of the example) with initial conditions \(t(0) = 0, \dot{t}(0) = \alpha, z(0) = h, \dot{z}(0) = 0\), resulting in the solution

\[
\begin{align*}
z &= -\frac{1}{2}g\tau^2 + h, \quad t = \alpha\tau + t_0, \\
E &= Mc^2\alpha, \quad p_z = -Mg\tau.
\end{align*}
\]

(1.18)

The invariant variable \(\tau\) replaces \(t\) in describing the dynamical evolution of the system. The generator of the motion

\[
K = \frac{p_z^2 - E^2/c^2}{2M} + mgz = \frac{1}{2}Mc^2\alpha^2 = \text{const},
\]

(1.19)

as required. The total energy of the particle in this case, including both increase of momentum and decrease of dynamical mass, is constant also. The effective particle mass \(\tilde{m}\) is given by

\[
\tilde{m} = \frac{1}{c} \sqrt{(E/c)^2 - p_z^2} = M\alpha \sqrt{1 - \frac{g^2\tau^2}{c^2\alpha^2}}.
\]

(1.20)

Expanding this out in the nonrelativistic limit \(c \to \infty\), one obtains (with \(\tau^2 = 2(h - z)/g\))

\[
\tilde{m} \approx M\alpha - \frac{Mg\alpha}{c^2}(h - z),
\]

(1.21)

and we recognize \(Mg(h - z)/c^2\) as the mass shift induced by the potential term. The factor \(\alpha\) arises due to the choice of initial conditions, i.e., for \(\tau = 0, \tilde{m} = M\alpha\), and not \(M\) (for \(\tau\) sufficiently large, under this unbounded potential, the quantity in the square root could become negative, and the particle could become tachyonic). Note that it is the mass of the particle which carries dynamical information (the total energy is constant, but the mass is “redshifted” by the potential) and that has the correspondence with nonrelativistic energy, through the mass-energy equivalence, that we observe in the laboratory. This point is discussed in more detail in, for example, refs. [31] and [32].
2 Ideal relativistic Bose gas without antiparticles

To describe an ideal gas of events obeying Bose-Einstein statistics in the grand canonical ensemble, we use the expression for the number of events found in [25],

\[ N = V^{(4)} \sum_{k^\mu} n_{k^\mu} = V^{(4)} \sum_{k^\mu} \frac{1}{e^{(E-\mu-\mu_K m^2)/M} - 1}, \]  

(2.1)

where \( V^{(4)} \) is the system’s four-volume and \( m^2 \equiv -k^2 = -k^\mu k_\mu \); \( \mu_K \) is an additional mass potential [25], which arises in the grand canonical ensemble as the derivative of the free energy with respect to the value of the dynamical evolution function \( K \), interpreted as the invariant mass of the system. In the kinetic theory [25], \( \mu_K \) enters as a Lagrange multiplier for the equilibrium distribution for \( K \), as \( \mu \) is for \( N \), and \( 1/T \) for \( E \). We shall see, in the following, how \( \mu_K \) plays a fundamental role in determining the structure of the mass distribution. In order to simplify subsequent considerations, we shall take it to be a fixed parameter.

To ensure a positive-definite value for \( n_{k^\mu} \), the number density of bosons with four-momentum \( k^\mu \), we require that

\[ m - \mu - \mu_K \frac{m^2}{2M} \geq 0. \]  

(2.2)

The discriminant for the l.h.s. of the inequality must be nonnegative, i.e.,

\[ \mu \leq \frac{M}{2\mu_K}. \]  

(2.3)

For such \( \mu \), (2.2) has the solution

\[ m_1 \equiv \frac{M}{\mu_K} \left( 1 - \sqrt{1 - \frac{2\mu \mu_K}{M}} \right) \leq m \leq \frac{M}{\mu_K} \left( 1 + \sqrt{1 - \frac{2\mu \mu_K}{M}} \right) \equiv m_2. \]  

(2.4)

For small \( \mu \mu_K/M \), the region (2.4) may be approximated by

\[ \mu \leq m \leq \frac{2M}{\mu_K}. \]  

(2.5)

One sees that \( \mu_K \) determines an upper bound of the mass spectrum, in addition to the usual lower bound \( m \geq \mu \). In fact, small \( \mu_K \) admits a very large range of off-shell mass, and hence can be associated with the presence of strong interactions [33].

Replacing the sum over \( k^\mu \) (2.1) by an integral, one obtains for the density of events per unit space-time volume \( n \equiv N/V^{(4)} \) [14],

\[ n = \frac{1}{4\pi^3} \int_{m_1}^{m_2} dm \int_{-\infty}^{\infty} d\beta \frac{m^3 \sinh^2 \beta}{e^{(m \cosh \beta - \mu - \mu_K m^2/2M)/T} - 1}, \]  

(2.6)
where $m_1$ and $m_2$ are defined in Eq. (2.4), and we have used the parametrization [26]

\[
p^0 = m \cosh \beta, \\
p^1 = m \sinh \beta \sin \theta \cos \phi, \\
p^2 = m \sinh \beta \sin \theta \sin \phi, \\
p^3 = m \sinh \beta \cos \theta,
\]

\[0 \leq \theta < \pi, \quad 0 \leq \phi < 2\pi, \quad -\infty < \beta < \infty.\]

In this paper we shall restrict ourselves to the case of high temperature alone:

\[T >> \frac{M}{\mu_K}.\]  \hfill (2.7)

It is then possible to use, for simplicity, the Maxwell-Boltzmann form for the integrand, and to rewrite (2.6) in the form

\[
n = \frac{e^{\mu/T}}{4\pi^3} \int_{m_1}^{m_2} m^3 \, dm \int_{-\infty}^{\infty} \sinh^2 \beta \, d\beta \, e^{-m \cosh \beta / T} e^{\mu_K m^2 / 2MT},
\]

which reduces, upon integrating out $\beta$, to [27]

\[
n = \frac{T e^{\mu/T}}{4\pi^3} \int_{m_1}^{m_2} dm \, m^2 K_1 \left( \frac{m}{T} \right) e^{\mu_K m^2 / 2MT},
\]

where $K_\nu(z)$ is the Bessel function of the third kind (imaginary argument). Since $\mu \leq m \leq m_2 \leq 2M/\mu_K$,

\[
\frac{\mu_K m^2}{2MT} \leq \frac{\mu_K (2M/\mu_K)^2}{2MT} = \frac{2M}{T \mu_K} << 1,
\]

in view of (2.7), and also

\[
\frac{\mu}{T} \leq \frac{m}{T} \leq \frac{2M}{T \mu_K} << 1.
\]

Therefore, one can neglect the exponentials in Eq. (2.9), and for $K_1(m/T)$ use the asymptotic formula [35]

\[
K_\nu(z) \sim \frac{1}{2} \Gamma(\nu) \left( \frac{z}{2} \right)^{-\nu}, \quad z << 1.
\]

Then, we obtain

\[
n \approx \frac{T^2}{4\pi^3} \int_{m_1}^{m_2} dm \, m = \frac{T^2}{2\pi^3} \left( \frac{M}{\mu_K} \right)^2 \sqrt{1 - \frac{2\mu \mu_K}{M}}.
\]  \hfill (2.13)
From this equation, one can identify the high-temperature mass distribution for the system we are studying, so that now

\[
\langle m^\ell \rangle = \int_{m_1}^{m_2} \frac{d\ell}{\ell} \frac{m^\ell \ell+1}{m^\ell+2} = \frac{2}{\ell+2} \frac{m_2^{\ell+2} - m_1^{\ell+2}}{m_2^2 - m_1^2}.
\]  

(2.14)

In particular,

\[
\langle m \rangle = \frac{4}{3} \frac{M}{\mu K} \left( 1 - \frac{\mu \mu K}{2M} \right),
\]  

(2.15)

\[
\langle m^2 \rangle = 2 \left( \frac{M}{\mu K} \right)^2 \left( 1 - \frac{\mu \mu K}{M} \right).
\]  

(2.16)

Extracting the joint distribution for \( \beta \) and \( m \) from (2.8) in the same way, we also obtain the average values of the energy and the square of the energy for high \( T \). The average energy is given by

\[
\langle E \rangle \equiv \langle m \cosh \beta \rangle \approx \frac{\int_{m_1}^{m_2} m^4 dm \sinh^2 \beta \cosh \beta d\beta e^{-m \cosh \beta/T}}{\int_{m_1}^{m_2} m^3 dm \sinh^2 \beta d\beta e^{-m \cosh \beta/T}}.
\]  

(2.17)

Integrating out \( \beta \), one finds

\[
\langle E \rangle \approx \frac{1}{4T} \frac{\int_{m_1}^{m_2} m^4 dm \sinh^2 \beta K_3(m/T) - K_1(m/T)}{\int_{m_1}^{m_2} m^2 K_1(m/T)} \approx 2T,
\]  

(2.18)

in agreement with refs. [25, 26, 27]. Similarly, one obtains

\[
\langle E^2 \rangle \equiv \langle m^2 \cosh^2 \beta \rangle \approx \frac{\int_{m_1}^{m_2} m^5 dm \sinh^2 \beta \cosh^2 \beta d\beta e^{-m \cosh \beta/T}}{\int_{m_1}^{m_2} m^3 dm \sinh^2 \beta d\beta e^{-m \cosh \beta/T}}
\]

\[= \frac{\int_{m_1}^{m_2} dm \{ m^4 K_1(m/T) + 3T m^2 K_2(m/T) \}}{\int_{m_1}^{m_2} m^2 K_1(m/T)} \approx 3T \frac{\int_{m_1}^{m_2} dm \ m^3 K_2(m/T)}{\int_{m_1}^{m_2} m^2 K_1(m/T)} \approx 6T^2.
\]  

(2.20)

Let us assume, as is generally done, that the average \( \langle p^\mu p^\nu \rangle \) has the form

\[
\langle p^\mu p^\nu \rangle = au^\mu u^\nu + bg^{\mu\nu},
\]  

(2.21)

where \( u^\mu = (1, 0) \) in the local rest frame. The values of \( a \) and \( b \) can then be calculated as follows: for \( \mu = \nu = 0 \) one has \( \langle (p^0)^2 \rangle = a - b \), while contraction of (2.21) with \( g^{\mu\nu} \)
gives \(-g^{\mu\nu}\langle p_\mu p_\nu \rangle = a - 4b\). The use of the expressions (2.20) for \(\langle (p^0)^2 \rangle \equiv \langle E^2 \rangle\), and (2.16) for \(-g^{\mu\nu}\langle p_\mu p_\nu \rangle \equiv \langle m^2 \rangle\) yields

\[
\begin{align*}
\begin{cases}
a - b &= 6T^2, \\
a - 4b &= 2(M/\mu_K)^2 (1 - \mu \mu_K/M),
\end{cases}
\end{align*}
\]

so that

\[
a = 8T^2 - \frac{2}{3} \left( \frac{M}{\mu_K} \right)^2 \left( 1 - \frac{\mu \mu_K}{M} \right),
\]

\[
b = 2T^2 - \frac{2}{3} \left( \frac{M}{\mu_K} \right)^2 \left( 1 - \frac{\mu \mu_K}{M} \right).
\]

For \(T \gg M/\mu_K\), it is possible to take \(a \approx 8T^2\), \(b \approx 2T^2\), and obtain, therefore,

\[
\langle p^\mu p^\nu \rangle \approx 8T^2 u^\mu u^\nu + 2T^2 g^{\mu\nu}.
\]

To find the expressions for the pressure and energy density in our ensemble, we study the particle energy-momentum tensor defined by the relation \[26\]

\[
T^{\mu\nu}(q) = \sum_i \int d\tau \frac{p_i^\mu p_i^\nu}{M/\mu_K} \delta^4(q - q_i(\tau)),
\]

in which \(M/\mu_K\) is the value around which the mass of the bosons making up the ensemble is distributed, i.e., it corresponds to the limiting mass-shell value when the inequality (2.3) becomes equality. Upon integrating over a small space-time volume \(\Delta V\) and taking the ensemble average, (2.25) reduces to \[26\]

\[
\langle T^{\mu\nu} \rangle = \frac{T_{\Delta V}}{M/\mu_K} n \langle p^\mu p^\nu \rangle.
\]

In this formula \(T_{\Delta V}\) is the average passage interval in \(\tau\) for the events which pass through the small (typical) four-volume \(\Delta V\) in the neighborhood of the \(R^4\)-point. The four-volume \(\Delta V\) is the smallest that can be considered a macrovolume in representing the ensemble. Using the standard expression

\[
\langle T^{\mu\nu} \rangle = (p + \rho)u^\mu u^\nu + pg^{\mu\nu},
\]

where \(p\) and \(\rho\) are the particle pressure and energy density, respectively, we obtain

\[
p \equiv p(\mu) = \frac{T_{\Delta V}}{\pi^3} \frac{M}{\mu_K} \sqrt{1 - \frac{2\mu \mu_K}{M} T^4}, \quad \rho = 3p.
\]

To interpret these results we calculate the particle number density per unit three-volume. The particle four-current is given by the formula \[26\]

\[
J^\mu(q) = \sum_i \int d\tau \frac{p_i^\mu}{M/\mu_K} \delta^4(q - q_i(\tau)),
\]

12
which upon integrating over a small space-time volume and taking the average reduces to
\[
\langle J^\mu \rangle = \frac{T_{\Delta V}}{M/\mu_K} n\langle p^\mu \rangle; \quad (2.30)
\]
then
\[
N_0 \equiv \langle J^0 \rangle = \frac{T_{\Delta V}}{M/\mu_K} n\langle E \rangle, \quad (2.31)
\]
so that
\[
N_0 \equiv N_0(\mu) = \frac{T_{\Delta V}}{\pi^3} \frac{M}{\mu_K} \sqrt{1 - \frac{2\mu\mu_K}{M}} T^3, \quad (2.32)
\]
and we recover the ideal gas law
\[
p = N_0 T. \quad (2.33)
\]
Since, in view of (2.4),
\[
\frac{2M}{\mu_K} \sqrt{1 - \frac{2\mu\mu_K}{M}} = \Delta m
\]
is a width of the mass distribution around the value \( M/\mu_K \), Eqs. (2.28),(2.32) can be rewritten as
\[
p = \frac{T_{\Delta V}\Delta m}{2\pi^3} T^4, \quad \rho = 3p, \quad (2.34)
\]
In ref. [36] we obtained the formulas for thermodynamic variables, under the assumption of narrow mass width, which depend on \( T_{\Delta V}\Delta m \) as well; the requirement that these results coincide with those of the usual on-shell theories implies the relation
\[
T_{\Delta V}\Delta m = 2\pi. \quad (2.35)
\]
One can understand this relation, up to a numerical factor, in terms of the uncertainty principle (rigorous in the \( L^2(R^4) \) quantum theory) \( \Delta E \cdot \Delta t \gtrsim 1/2 \). Since the time interval for the particle to pass the volume \( \Delta V \) (this smallest macroscopic volume is bounded from below by the size of the wave packets) \( \Delta t \approx E/M \Delta \tau \), and the dispersion of \( E \) due to the mass distribution is \( \Delta E \sim m\Delta m/E \), one obtains a lower bound for \( T_{\Delta V}\Delta m \) of order unity.

Thus, with (2.35) holding, the formulas (2.34) reduce to
\[
p = \frac{T^4}{\pi^2}, \quad \rho = 3p, \quad (2.36)
\]
\[
N_0 = \frac{T^3}{\pi^2}, \quad (2.37)
\]
\footnote{In c.g.s. units, this relation has a factor \( \hbar/e^2 \) on the right hand side.}
which are the standard expressions for high temperature [37]. The formulas for characteristic thermodynamic quantities and the equation of state for a relativistic gas of off-shell events have the same form as those of the relativistic gas of on-shell particles. They coincide with them (under the condition (2.35)) in the narrow mass shell limit, except for the expression for the average energy which takes the value $2T$ in the relativistic gas of events, in contrast to $3T$, as for the high-temperature limit of the usual theory [23]. Experimental measurement of average energy at high temperature can, therefore, affirm (or negate) the validity of the off-shell theory. There seems to be no empirical evidence which distinguishes between these results at the present time. The quantity $\sigma = M_0 c^2 / k_B T$, a parameter which distinguishes the relativistic from the nonrelativistic regime (see, e.g., [25]) is very large for $M_0$ of the order of the pion mass, at ordinary temperatures; the ultrarelativistic limit corresponding to $\sigma$ small becomes a reasonable approximation for $T \gtrsim 10^{12}$ K.

3 Antiparticles and condensation

The introduction of antiparticles into the theory as the CPT conjugate of negative energy events leads, by application of the arguments of Haber and Weldon [10], or Actor [38], to a change in sign of $\mu$ in the distribution function for antiparticles. We therefore write down the following relation which represents the analog of the formula (1.2):

$$N = V^{(4)} \sum_{k\mu} \left[ \frac{1}{e^{(E-\mu-\mu_K \frac{m^2}{2M})/T} - 1} - \frac{1}{e^{(E+\mu-\mu_K \frac{m^2}{2M})/T} - 1} \right].$$

With respect to the determination of the sign of the second term, let us consider a space-time picture in which we have many world lines, generated by events moving monotonically in the positive $t$ direction. The addition of a particle-antiparticle pair which annihilates corresponds to the addition of a world line which is generated by an event initially moving in the positive direction of time to some upper bound, $t_0$, where annihilation takes place, and returning in the negative direction of time. At times later than $t_0$ the total particle number is unaffected. At times earlier than $t_0$, a particle and antiparticle are added to the total particle number. Since, as also assumed by Haber and Weldon [10], the total particle number is a conserved quantity, the antiparticle trajectory must be counted with a sign opposite to that of the particle trajectory. The second term in (3.1), counting antiparticles, must therefore carry a

\[4\] As for the nonrelativistic theory, the “free” distribution functions describe quasiparticles in a form which takes interactions into account entering through the chemical potential. By definition, good quasiparticles are not frequently emitted or absorbed; we therefore consider the (quasi-) particles and antiparticles as two species. Since the particle number is determined by the derivative of the free energy with respect to the chemical potential, $\mu$ must change sign for the antiparticles [10]. Similarly, the average mass (squared) is obtained by the derivative with respect to $\mu_K$ [25]; since the mass (squared) of the antiparticle is positive, $\mu_K$ does not change sign.
negative sign. We require that both $n_{k\nu}$ terms in Eq. (3.1) be positive definite. In this way we obtain the two quadratic inequalities,

\[
\begin{align*}
  m - \mu - \mu_K \frac{m^2}{2M} &\geq 0, \\
  m + \mu - \mu_K \frac{m^2}{2M} &\geq 0,
\end{align*}
\]  

(3.2)

which give the following relation representing the nonnegativeness of the corresponding discriminants:

\[
- \frac{M}{2\mu_K} \leq \mu \leq \frac{M}{2\mu_K}.
\]  

(3.3)

It then follows that we must consider the intersection of the ranges of validity of the two inequalities (3.2). Indeed, if each inequality is treated separately, there would be some values of $m$ for which one and not another would be physically acceptable. One finds the bounds of this intersection region by solving these inequalities, and obtains\(^5\)

\[
\frac{M}{\mu_K} \left( 1 - \sqrt{1 - \frac{2|\mu|\mu_K}{M}} \right) \leq m \leq \frac{M}{\mu_K} \left( 1 + \sqrt{1 - \frac{2|\mu|\mu_K}{M}} \right),
\]  

(3.4)

which for small $|\mu|\mu_K/M$ reduces, as in the no-antiparticle case (2.5), to

\[
|\mu| \leq m \leq \frac{2M}{\mu_K}.
\]  

(3.5)

Replacing the summation in (3.1) by integration, we obtain a formula for the number density:

\[
n = \frac{1}{4\pi^3} \int_{m_1}^{m_2} dm \int_{-\infty}^{\infty} \sinh^2 \beta d\beta \left[ \frac{1}{e^{(m \cosh \beta - \mu - \mu_K \frac{m^2}{2M})/T} - 1} - \frac{1}{e^{(m \cosh \beta + \mu - \mu_K \frac{m^2}{2M})/T} - 1} \right],
\]  

where $m_1$ and $m_2$ are defined in Eq. (3.4), which for large $T$ reduces, as above, to

\[
n = \frac{e^{\mu/T} - e^{-\mu/T}}{4\pi^3} T \int_{m_1}^{m_2} dm \ m^2 K_1 \left( \frac{m}{T} \right) e^{\mu_K m^2/2MT}.
\]  

(3.6)

Now, using the estimates (2.10),(2.11), and $\sinh(\mu/T) \approx \mu/T$ for $\mu/T << 1$, we obtain (in place of (2.13)) the net event charge

\[
n = \frac{1}{\pi^3} \left( \frac{M}{\mu_K} \right)^2 \sqrt{1 - \frac{2|\mu|\mu_K}{M}} \mu T.
\]  

(3.7)

\(^5\)This is actually the solution of one of the inequalities (3.2) (the most restrictive), depending on the sign of $\mu$.  

15
The pressure and energy density are obtained by the sum particle and antiparticle contributions (proportional to $\exp(\pm \mu/T)$, with the number density (3.7). To second order in $(\mu/T)^2$, one finds

$$p = 2p(|\mu|),$$

$$\rho = 2\rho(|\mu|),$$

where $p(\mu)$ and $\rho(\mu)$ are given by (2.28) with $\mu$ replaced by $|\mu|$. On the other hand, from (2.31) and (3.7), one finds

$$N_0 = 2\frac{T_{\Delta V} M}{\pi^3 \mu_K} \sqrt{1 - \frac{2|\mu|\mu_K}{M} \mu T^2},$$

(3.8)

where the factor of $2\mu/T$, as compared to (2.32), arises from the difference between the factors $\exp(\pm \mu/T)$ (the sign of $\mu$ indicates whether particles or antiparticles predominate). One then obtains the following expressions for the Bose gas including both particles and antiparticles

$$p = T_{\Delta V} \Delta m \frac{2T^4}{\pi^2}, \quad \rho = 3p,$$

(3.9)

$$N_0 = T_{\Delta V} \Delta m \frac{2T^2}{\pi^2} \mu.$$

(3.10)

We now wish to show that the dynamical properties of the current, which follow from the relativistic canonical equations of motion, are consistent with the thermodynamic relation

$$N_0 = \frac{N}{V};$$

(3.11)

where $N$ is the number of bosons in a three-dimensional box of volume $V$. Since the event number density $n$ is, by definition,

$$n = \frac{N}{V^{(4)}} = \frac{N}{V \Delta t},$$

where $\Delta t$ is the (average) extent of the ensemble along the $q^0$-axis (as in our discussion after (2.35)), one has

$$N_0 = n \Delta t.$$

\[\text{If we did not neglect indistinguishability of bosons at high temperature, we would obtain, instead of (2.37),}
N_0 = \frac{T^3}{\pi^3} \ell_3(e^{\mu/T}), \text{ where } \ell_3(z) \equiv \sum_{s=1}^{\infty} z^s/s^3 \text{ is the polylogarithm, so that, for the system including both particles and antiparticles, } N_0 = \frac{T^3}{\pi^3} [\ell_3(e^{\mu/T}) - \ell_3(e^{-\mu/T})]. \text{ It then follows from the properties of the polylogarithms that, for } x \equiv |\mu|/T << 1, \ell_3(e^x) - \ell_3(e^{-x}) \approx \frac{x^3}{3} x, \text{ so that, we would obtain, instead of (3.10), } N_0 = \mu T^2/3, \text{ which coincides with Haber and Weldon’s Eq. (1.5).}\]
The equation of motion (1.9) for $q^0$ (with $M/\mu_K$, the central value of the mass distribution, instead of $M$, which corresponds to a change of scale parameter in the expression (1.8) for the generalized Hamiltonian $K$),

$$\frac{dq^0_i}{d\tau} = \frac{p^0_i}{M/\mu_K},$$

upon averaging over the whole ensemble, reduces to

$$\frac{\Delta t}{T_{\Delta V}} = \frac{\langle E \rangle}{M/\mu_K}, \quad (3.13)$$

where $T_{\Delta V}$ is the average passage interval in $\tau$ used in previous consideration. Then, in view of (3.12),(3.13), one obtains the equation (2.31).

### 3.1 Relativistic Bose-Einstein condensation

Since in the particle-antiparticle case, $N_{\text{rel}} \equiv N - \bar{N}$, where $N$ and $\bar{N}$ are the numbers of particles and antiparticles, respectively, is a conserved quantity, according to the arguments of Haber and Weldon [10] pointed out in Section 1, and our discussion above, $N_0 = N_{\text{rel}}/V$ is also a conserved quantity, so that it makes sense to talk of $|N_{\text{rel}}|$ bosons in a spatial box of the volume $V$. Therefore, in Eq. (3.10) $N_0$ is a conserved quantity, so that, the dependence of $\mu$ on temperature is defined by (we assume that $N_0$ is continuous at the phase transition)

$$\mu = \frac{2\pi}{T_{\Delta V} \triangle m} \frac{\pi^2 N_0}{2T^2}. \quad (3.14)$$

For $T$ above some critical temperature, one can always find $\mu$ satisfying (3.3) such that the relation (3.14) holds; no such $\mu$ can be found for $T$ below the critical temperature. The value of the critical temperature is defined by putting $|\mu| = M/2\mu_K$ in (3.14). In the narrow mass-shell limit, inserting (2.35), one obtains

$$T_c = \pi \sqrt{\frac{|N_0|}{M/\mu_K}}. \quad (3.15)$$

For $|\mu| = M/2\mu_K$, the width of the mass distribution is zero, in view of (3.4), and hence the ensemble approaches a distribution sharply peaked at the mass-shell value $M/\mu_K$. The fluctuations $\delta m = \sqrt{\langle m^2 \rangle - \langle m \rangle^2}$ also vanish. Indeed, as follows from (2.15),(2.16) with $\mu$ replaced by $|\mu|$, and (3.14),(3.15),

$$\delta m = \frac{M}{3\mu_K} \sqrt{2 - \left(\frac{T_c}{T}\right)^2 - \left(\frac{T_c}{T}\right)^4}, \quad (3.16)$$
so that, at $T = T_c$, $\delta m = 0$. It follows from (3.16) that for $T$ in the vicinity of $T_c$ ($T \geq T_c$),

$$\delta m \simeq \frac{M}{3\mu_K} \sqrt{\frac{6}{T_c}} \sqrt{T - T_c},$$

(3.17)
as for a second order phase transition, for which fluctuations go to zero smoothly.

We note that Eqs. (2.36),(2.37) do not contain explicit dependence on the chemical potential, and hence no phase transition is induced. In fact, at lower temperature (or small $\mu_K$) one or the other of the particle or antiparticle distribution dominates, and one returns to the case of the high-temperature strongly interacting gas. The remaining phase transition is the usual low-temperature Bose-Einstein condensation discussed in the textbooks.

One sees, with the help of (3.4), that the expression for $n$ (3.7) can be rewritten as

$$n = \frac{1}{2\pi^3} \frac{M}{\mu_K} \Delta m \mu T,$$

(3.18)
since at $T = T_c$, $\Delta m = 0$, it follows that $n = 0$ at all temperatures below $T_c$. Therefore, the behaviour of an ultrarelativistic Bose gas including both particles and antiparticles, which is governed by the relation (3.14), can be thought of as a special type of Bose-Einstein condensation to a ground state with $p^\mu p_\mu = -(M/\mu_K)^2$ (this ground state occurs with zero weight in the integral (3.6)). In such a formulation, every state with temperature $T > T_c$, given by Eq. (3.6), should be considered as an off-shell excitation of the on-shell ground state. At $T = T_c$, all such excitations freeze out and the distribution becomes strongly peaked at a definite mass, i.e., the system undergoes a phase transition to the on-shell sector. Note that, for $n = 0$, Eq. (3.12) gives $\Delta t = \infty$. Then, since $\langle E \rangle \sim T$, one obtains from (3.13) that $T_{\Delta V} = \infty$ (this relation can be also obtained from (2.35) for $\Delta m = 0$), which means that in the mean, all the events become particles.

As the distribution function enters the on-shell phase at $T = T_c$, the underlying off-shell theory describes fluctuations around the sharp mean mass. This phenomenon provides a mechanism, based on equilibrium statistical mechanics, for understanding how the general off-shell theory is constrained to the neighborhood of a sharp universal mass shell for each particle type. At temperatures below $T_c$, the results of the theory for the main thermodynamic quantities coincide with those of the usual on-shell theories.

In order that our considerations be valid, the relation $T_c >> M/\mu_K$ must hold; this relation reduces, with (3.15), to

$$|N_0| >> \frac{1}{\pi^2} \left( \frac{M}{\mu_K} \right)^3.$$

(3.19)

For $M/\mu_K \sim m_\pi \approx 140$ MeV, this inequality yields $N_0 >> 3 \cdot 10^5$ MeV$^3$. Taking $N_0 \sim 5 \cdot 10^6$ MeV$^3$, which corresponds to temperature $\sim 350$ MeV, in view of (2.37),
one gets $T_c \sim 550 \text{ MeV} \simeq 4m_\pi$.

If $\mu_K$ is very small, it is difficult to satisfy (3.19) and the possibility of such a phase transition may disappear. This case corresponds, as noted above, to that of strong interactions and is discussed in succeeding paper [40].

4 Concluding remarks

We have considered the ideal relativistic Bose gas within the framework of a manifestly covariant relativistic statistical mechanics, taking account of antiparticles. We have shown that in such a particle-antiparticle system at some critical temperature $T_c$ a special type of relativistic Bose-Einstein condensation sets in, which corresponds to a phase transition from the sector of relativistic mass distributions to a sector in which the boson mass distribution peaks at a definite mass. The results which can be computed from the latter coincide with those obtained in a high-temperature limit of the usual on-shell relativistic theory.

The relativistic Bose-Einstein condensation in particle-antiparticle system considered in the present paper can represent (as for the Galilean limit $c \to \infty$ [36]) a possible mechanism of acquiring a given sharp mass distribution by the particles of the system, as a phase transition between the corresponding sectors of the theory. Since this phase transition can occur at an ultrarelativistic temperature, it might be relevant to cosmological models. The relativistic Bose-Einstein condensation considered in the present paper may also have properties which could be useful in the study of relativistic boson stars [41]. These and the other aspects of the theory are now under further investigation.

The extension and generalization of Bose-Einstein condensation to curved space-times and space-times with boundaries, for which the work reported here may have constructive application, has also been the subject of much study. The non-relativistic Bose gas in the Einstein static universe was treated in ref. [1]. The generalization to relativistic scalar fields was given in refs. [12, 13]. The extension to higher dimensional spheres was given in ref. [14]. Bose-Einstein condensation on hyperbolic manifolds [45], and in the Taub universe [46] has also been considered. More recently, by calculating the high-temperature expansion of the thermodynamic potential when the boundaries are present, Kirsten [47] examined Bose-Einstein condensation in certain cases. Later work of Toms [48] showed how to interpret Bose-Einstein condensation in terms of symmetry breaking, in the manner of flat space-time calculations [11, 13]. The most recent study by Lee et al. [49] showed how interacting scalar fields can be treated. Bose-Einstein condensation for self-interacting complex scalar fields was considered in ref. [50]. It is to be hoped that the techniques developed here can contribute to the development of this subject as well.
