patients had lower blood urea, serum alkaline phosphatase and serum albumin. Residual renal function, duration of peritoneal dialysis and presence of diabetes and other co-morbid conditions did not correlate significantly with depression.

CONCLUSION: We document a high prevalence of depression among Indian PD patients. Depressed patients had evidence of poor dietary protein intake and poorer nutrition as evidenced by lower serum urea and albumin. Further studies looking at effect of early detection and treatment of depression on PD outcome are warranted.

INTRODUCTION
With the increasing incidence and prevalence of end stage renal disease (ESRD) search for factors that are amenable to therapy and which adversely affect patient outcome and quality of life (QOL) is gathering momentum. This has brought forth in focus psychosocial factors among ESRD patients [1-3]. Depression is recognized as the most common psychological problem encountered among patients with ESRD [4-7]. Studies have suggested that depressive symptoms occur in 25-50% of patients maintained on dialysis therapy [8-10]. The studies looking at depression among dialysis patients are mainly from the United States and Europe and have been performed predominantly among HD patients. Few studies among patients on chronic peritoneal dialysis (PD) have correlated depression with poor patient survival and increased risk of peritonitis [6,7]. Race and geographical area have been shown to be important factors affecting
depression among ESRD patients\[4\]. In a study from Korea, the prevalence of depression among PD patients was found to be 75%\[5\] as opposed to 33-50% reported from western studies\[6\]. Also, only a few studies have looked at the socio-economic and medical factors associated with depression in these patients. Identifying these factors can help in determining the patients who are at a higher risk of developing depressive symptoms. The present study was therefore undertaken to look at the prevalence of depression among Indian PD patients and the factors associated with depression.

### MATERIALS AND METHODS

All patients on PD for ≥ 6 months, who consented for screening for depression, were enrolled. Beck Depression Inventory (BDI) was used to screen the patients. The BDI is a 21-item self-report rating inventory measuring characteristic attitudes and symptoms of depression. The 21 items are answered on a 4 point Likert scale in which zero represents the absence of problem and 3 represents an extreme problem with a total ranging from 0-63. The patients were classified as being normal (BDI score ≤ 10), having mild mood disturbance (BDI score 11-16), having moderate depression (BDI score 17-30), or having severe depression (BDI score > 30). The patients filled the BDI questionnaire themselves or it was read out to them in case of poor vision or if they were illiterate. BDI was chosen since this has been the most used and validated score among ESRD and PD patients\[3,9\]. The baseline demographic profile of these patients at the time of BDI administration was recorded. The duration of dialysis, urine output, presence of co-morbidities like diabetes mellitus (DM) and coronary artery disease (CAD), were also recorded along with bio-chemical profile including blood urea, serum creatinine, serum albumin and hemoglobin.

### Statistical analysis

The statistical analysis was performed using Stata version 8 (Texas, United States). The results were expressed as mean ± SD wherever appropriate. Univariate and multivariate regression analysis was done to calculate adjusted odds ratio in depressed compared non-depressed patients.

### RESULTS

Of the 89 patients eligible for the study, 82 patients consented for the same (92.1%). Baseline profile of the 82 patients who completed BDI is shown in Table 1. The mean age of the study population was 51.5 ± 11.5 years. In the study population there were 64.6% males and 34% diabetics. The mean duration on PD was 47.6 ± 21.1 months (range 7-105 months). The mean BDI score of the study population was 19.1. 19 (23.2%) patients reported no depression (BDI score ≤ 10), 13 (15.9%) reported having mild mood disturbance (BDI score 11-16), while 50 (61%) reported having depression having BDI scores of ≥ 17. 10 patients (12.2%) had severe depression (BDI score > 30). All the patients detected having severe depressive symptoms were encouraged to undergo a formal psychiatric evaluation. However, only 4 patients opted for same and only 2 subsequently had a regular psychiatry follow-up.

Table 1 shows the odds ratio (OR) of various parameters between depressed and non-depressed patients. On univariate analysis (unadjusted OR) depressed patients were found to have lower body mass index (OR 0.36, P value 0.03), blood urea (OR 0.28, P value 0.01), serum alkaline phosphatase (OR 0.32, P value 0.02), total serum protein (OR 0.33, P value 0.02), serum albumin (OR 0.12, P value > 0.01) and serum uric acid (OR 0.34, P value 0.02). After multivariate regression analysis (adjusted OR), parameters that were still found to be lower in depressed patients were blood urea (OR 0.19, confidence interval 0.06-0.65), serum albumin (OR 0.15, confidence interval 0.04-0.51) and serum alkaline phosphatase (OR 0.15, confidence interval 0.04-0.57).

### DISCUSSION

Depression is ranked fourth among disabling diseases affecting people worldwide\[10\] and is the most common psychological problem observed in patients with ESRD\[1\]. PD being a domiciliary therapy requires patient to organize their own care and therefore it can be expected that depression would play a crucial role in influencing the complication rate and outcome associated with this therapy. Studies from the United States have reported incidence of depressive symptoms in PD population to be around 50%\[7\]. However, prevalence of depression in PD patients has shown a wide variation depending upon the criteria used and patient population studied, with Kim et al\[8\] reporting a prevalence of 75% in their Korean PD population. In our study among Indian PD patients, we found a high prevalence of self-reported depressive symptoms among our PD patients (61%), with around 12% reporting severe depression and a mean BDI score of 19.1. Difference in social and economic background, besides race and ethnicity could be the factors contributing to this increased incidence of depression among our patients as compared to other western studies. We also found a marked reluctance in patients to undergo a regular psychiatric opinion and follow-up with only 40% of severely depressed patients agreeing for a formal psychiatric evaluation and only 20% subsequently having a regular follow-up. Wuerth et al\[9\] similarly found that 55% of their depressed PD patients refused further psychiatric evaluation and subsequently 32% discontinued therapy after a brief follow-up. Reluctance for anti-depressant therapy and high drop-out rates have also been noted in depressed patients without major medical...
illness\(^{(1)}\). This can partly explain the initial reluctance and high drop out rate in our set of patients who in addition to depression have complex medical illness and therapy. We could not find a significant difference between the demographic and socio-economic status of the depressed as compared to non-depressed patients. Most other studies have not found any demographic factor to be significantly associated with depression\(^{(7,9)}\), while Einwohner et al\(^{(6)}\) have found increasing age as a significant factor affecting depression. Of the initial medical profile we found that depression did not correlate with duration on PD, residual urine output, and presence of co-morbidities like diabetes and cardiovascular disease (CAD). Among the dialysis patients the association between depression and co-morbidities like DM, CAD and PVD is not certain. Some authors have found the increasing co-morbidity profile to be positively correlated with depression\(^{(6,7)}\), while others have found no significant correlation between the two\(^{(9)}\). We found that depressed patients had lower dietary protein intake as evidenced by lower blood urea and serum albumin in these patients. The association between depression and nutritional parameters in dialysis patients is more consistent. Recent studies from Turkey have also linked depression in dialysis

| Table 2 | Odds Ratio of various parameters between depressed and non-depressed PD patients. |
|---------|---------------------------------------------------------------------------------|
| Variables | BDI ≤ 16 | BDI > 16 | P-value | Unadjusted OR (95% CI) | Adjusted OR (95% CI) |
| Age (years) | | | | | |

patients (both HD and PD) with a decreased hemoglobin and serum albumin and increased C-reactive protein (CRP)\[1,2,13\]. Another earlier study in Korean HD patients also noted that depression was closely related to the nutritional status\[14\]. Friend et al have looked at link between depression and serum albumin\[15\]. They in their 72-dialysis patients (32 HD and 40 PD) noted that depressive symptoms preceded the fall in serum albumin, while there was no association between initial serum albumin level and development of depression. Koo et al\[16\] have recently shown an improvement in nutritional status in HD patients subsequent to successful completion of anti-depressant treatment for 8 weeks. These studies suggest that depression causes malnutrition. The biological mechanisms by which depression might lead to malnutrition and lower albumin levels are not entirely clear. Depression is commonly associated with decreased food intake, which can aggravate malnutrition in chronic dialysis patients\[17\]. There also is evidence that major depression is accompanied by activation of the inflammatory response system, and pro-inflammatory cytokines may have a role in causation of depression\[18,19\]. Thus pro-inflammatory cytokines can be a common link between depression and malnutrition in dialysis patients.

Our study however has few limitations. It’s a single center, cross-sectional study with a small sample size; therefore the results need to be confirmed by larger multi-centric study. Depressive symptoms in dialysis patients may wax and wane with time and hence single point assessment of depressive symptoms might not be representative of subsequent events. However, the high prevalence of depression noted in our study, indicates an urgent need to look at depression in our PD population. We also have not looked at the effect of anti-depressant therapy if any on outcome measures. Also being a cross-sectional study we cannot assign any cause effect relationship from our study.

To conclude, our study suggests a high prevalence of depression (61%) among Indian PD patients, with depressed patients having lower serum urea and albumin indicating poorer dietary protein intake and malnutrition. These results advocate for inclusion of screening for depression as a part of routine care provided to PD patients. Further studies are however required to look at the effect of regular screening for depression and its treatment on long term outcome and infectious complications.

CONFLICT OF INTERESTS

Declaration of interest: The authors report no conflicts of interest. The authors alone are responsible for the content and writing of the paper.

Compliance with ethical standards: The institutional ethics committee approved the study and written informed consent was obtained from all the study subjects.
