(Dated: March 22, 2022)

We discuss the conductance of a Luttinger liquid interrupted by a quantum dot containing a single resonant level. Using bosonisation and re-fermionisation methods, we find a mapping to a Kondo-type problem which possesses a non-trivial Toulouse-type solvable point. At this point, we obtain an analytic expression for the non-linear current-voltage characteristics and analyse the differential conductance and the width of the resonance peak as functions of bias and gate voltages, temperature, and barrier asymmetry. We also determine the exact scaling function for the linear conductance.

PACS numbers: 73.63.-b, 71.10.Pm, 73.63.Kv

The field of one-dimensional interacting metallic systems recently experienced another revival as single–wall carbon nanotubes (SWNTs) have been found to display transport properties consistent with the Luttinger liquid (LL) theory [1]. While the electrical transport through clean SWNTs has been investigated in different independent experiments, the transport properties of SWNTs with impurities (or in more complicated set-ups) are still to be studied in detail. Progress was recently made in this direction: in [2] the manufacture of quantum dots on the nanotube basis was reported. Surprisingly, the authors found that the transport is dominated by a coherent transmission (or resonant tunnelling) in a wide parameter range.

The presence of a resonant level is known to enhance conductance. Indeed, for non-interacting electrons the local level hybridises with the conduction band causing a Lorentzian shaped peak in the density of states (the conductance being related to the Breit–Wigner scattering cross-section via the Landauer formula). Unless the system is exactly at resonance, the picture remains qualitatively the same for the case of interacting electrons, even LLs [3]. Therefore one expects the conductance to increase upon lowering the temperature. On the other hand, at low temperatures, the conductance is known to vanish (unless exactly at resonance) due to the effective enhancement of backscattering processes specific for the LLs. Hence a non-monotonic behaviour of the linear conductance as a function of temperature. The limiting cases has been thoroughly studied in Refs. [3, 4, 5, 6] but the full description of the cross-over remains an open problem.

Recently, Nazarov and Glazman (NG) calculated the cross-over conductance in the weak electron-electron interaction limit (when the LL parameter $g$ is close to 1) by using the Landauer type approach supplemented by renormalisation group [7]. In this paper, we wish to discuss the opposite limit of strong interactions, which is relevant for such systems as SWNTs. We shall concentrate on the special value of the coupling $g = 1/2$ and present an explicit solution of the problem at this point. At this particular value of the LL parameter and when the resonant level energy is tuned to match the equilibrium chemical potentials in the leads, the resonant tunnelling process is marginally relevant and its amplitude increases logarithmically upon lowering the energy scale [8]. It turns out that at low temperatures in the linear regime (i.e. in the limit of small bias voltage) the sequential tunnelling dominates the transport for $g < 1/2$, while above that value the resonant transmission wins over [3, 8]. Hence, apart from being supplementary to NG results, the exact solution at $g = 1/2$ yields insights into the interplay between these two transport mechanisms.

We model the system by a resonant level (which can also be regarded as a single state quantum dot, so we use both terms) coupled to interacting leads, which is described by the following Hamiltonian (we ignore the spin degree of freedom throughout the paper),

$$H = H_K + H_t + H_C,$$

where $H_K$ is the kinetic part, $H_K = \Delta d^\dagger d + \sum_{i=R,L} H_0[\psi_i]$, describing the the electronic degrees of freedom in the leads $H_0[\psi_i]$, and the resonant level with energy $\Delta$ with the corresponding electron operators being $d^\dagger, d$. The dot can be populated from either of the two leads ($i = R,L$) via electron tunnelling with amplitudes $\gamma_i$, $H_t = \sum_i \gamma_i [d^\dagger \psi_i(0) + h.c.]$. Here $H_C$ describes the electrostatic Coulomb interaction between the leads and the dot, $H_C = \lambda_C d^\dagger d \sum_i \psi_i^\dagger(0) \psi_i(0)$. This interaction is a new ingredient we have introduced, absent in [3, 4, 5, 6]. It does not, however, affect the universality as we shall show. The contacting electrodes are supposed to be one-dimensional half-infinite electron systems. We model them by chiral fermions living in an infinite system: the negative half-axis then describes the particles moving towards the boundary, while the positive half-axis carries electrons moving away from the end of the system. In the bosonic representation $H_0[\psi_i]$ are diagonal even in presence of interactions (for a recent review see e.g. [3]: we set the renormalised Fermi velocity $v = v_F/g = 1$, the bare velocity being $v_F$: $H_0[\psi_i] = (4\pi)^{-1} \int dx [\partial_x \phi_i(x)]^2$. Here the phase fields $\phi_i(x)$ describe the slow varying spatial component of the electron...
density (plasmons), \( \psi^\dagger(x)\psi(x) = \partial_x \phi(x)/2\pi \sqrt{g} \). The
electron field operator at the boundary is given by \( \psi_\alpha(0) = e^{i\phi(0)/\sqrt{\gamma}}/\sqrt{2\pi a_0} \), where \( a_0 \) is the lattice
constant of the underlying lattice model. Here \( g \) is the conventional LL parameter (coupling constant) [3, 4]. In the
chiral formulation the bias voltage amounts to a difference in the densities of the incoming particles in both
channels far away from the constriction [9]. The current is then proportional to the difference between the
densities of incoming and outgoing particles within each channel.

To the best of our knowledge, Hamiltonian (6) cannot be solved exactly even in the \( g = 1 \) case as long as
\( \lambda_C \) remains finite. However, after a transformation of \( d^\dagger \) and \( d \) operators to the spin representation of the form
\( S_x = (d^\dagger + d)/2 \), \( S_y = -i(d^\dagger - d)/2 \), \( S_z = d^\dagger d - 1/2 \), one immediately observes that the \( \lambda_C \) term is analogous to the \( S_z \)-spin density coupling in the Kondo problem.

The latter is known to be explicitly solvable at a particular value of the longitudinal coupling: the Toulouse limit
(see e.g. [4]). Let us perform a similar calculation. As a first step we introduce new symmetric and antisymmetric fields \( \phi_{\pm} = (\phi_L \pm \phi_R)/\sqrt{2} \), which still fulfill the bosonic commutation relations. Then we apply the transformation \( H' = U^\dagger H U \) with \( U = \exp(iS_z \phi_+ / \sqrt{2g}) \) [10], which changes the kinetic and the Coulomb coupling parts of the full Hamiltonian to (we drop a constant contribution)
\[
H'_{K} + H'_{C} = H_K + (\lambda_C/\pi \sqrt{2g} - \sqrt{2/g} S_z \delta \phi_+ (0)) ,
\]
and the tunnelling part (terms containing \( \gamma_i \) ) to
\[
H'_i = (2\pi a_0)^{-1/2} \left[ S_+ (\gamma_L e^{i\phi_+/\sqrt{2g}} + \gamma_R e^{-i\phi_-/\sqrt{2g}}) + \gamma_L e^{-i\phi_-/\sqrt{2g}} + \gamma_R e^{i\phi_+/\sqrt{2g}} S_- \right] ,
\]
where \( S_{\pm} = S_x \pm iS_y = d^\dagger d \). At the point \( g = 1/2 \) one can re-fermionise the problem by defining new operators
\[
\psi_{\pm} = e^{i\phi_\pm}/\sqrt{2\pi a_0} ,
\]
which fulfill standard fermionic commutation relations. With the help of the particle density operator
\( \psi_0^\dagger \psi_0 = \partial_x \phi_\pm /2\pi \) we can immediately write down the reformerionised Hamiltonian,
\[
H = H_0[\psi_{\pm}] + (\lambda_C - 2\pi) 2S_0 \psi_0^\dagger \psi_0 + \Delta S_z + S_+ (\gamma_L \psi_- + \gamma_R \psi_0^\dagger) + (\gamma_L \psi_0^\dagger + \gamma_R \psi_-) S_- .
\]
In the case of the symmetric coupling \( \gamma_L = \gamma_R \) this Hamiltonian is similar to that of the two-channel Kondo
problem and, at the Toulouse point \( \lambda_C = 2\pi \), can be solved exactly (out of equilibrium) using the method of
Ref. [11]. The novel ingredient in the following analysis is the extension to the asymmetric case. To take advantage of the Toulouse point we set the Coulomb coupling amplitude to \( 2\pi \) in what follows. This not only removes the four fermion interaction but decouples the ‘\( \pm \)’ channels making the ‘\( + \)’ channel free (i.e. decoupled from the dot variables).

As we already mentioned, due to the linear dispersion relation, the current through the system is proportional
to the difference between the densities of particles moving towards the dot and away from it in either of the
channels. Due to the chiral geometry we then have \( I \sim \psi_0^\dagger \psi_L(-\infty) - \psi_0^\dagger \psi_L(\infty) \), which, being transformed to ‘\( \pm \)’ channels, results in \( I \sim \psi_0^\dagger \psi_-(-\infty) - \psi_0^\dagger \psi_-(-\infty) \).
Since the ‘\( + \)’ channel is free, it doesn’t contribute to the above formula. As the ‘\( -\)’ channel is also free when away from the dot, in order to calculate the current we only need to know the scattering matrix of ‘\( -\)’-fermions determined by Hamiltonian (6). The chemical potential of the incoming particles is determined by the bias voltage. Hence, the current is given by (we measure voltage in energy units, i.e. set \( e = 1 \))
\[
I(V) = G_0 \int d\omega T(\omega)[n_F(\omega - V) - n_F(\omega)]
\]
where \( n_F \) denotes the Fermi distribution function and \( D(\omega) = 1 - T(\omega) \) is the energy dependent penetration coefficient of the ‘\( -\)’-particles from \( x < 0 \) to \( x > 0 \). The pre-factor \( G_0 = e^2/\hbar \) is fixed by the requirement that at zero transmission \( D(\omega) = 0 \) (or perfect transmission of the whole structure) one obtains the correct conductance.

The easiest way to obtain the transmission coefficient is the equations of motion method. Since we have two
types of operators: for the electrons of the ‘\( -\)’ channel and for the resonance level (we go back to the original
\( d, d^\dagger \) operators), we need two equations of motion,
\[
i\partial_x \psi_\pm (x) = -i\partial_x \psi_\pm (x) + \delta(x)(\gamma_L d - \gamma_R d^\dagger) ,
i\partial_t d = \Delta d + \gamma_L \psi_- (0) + \gamma_R \psi_0^\dagger (0) .
\]
Integrating the first one around \( x = 0 \) we obtain
\[
i[\psi_- (0^+) - \psi_- (0^-)] = \gamma_L d - \gamma_R d^\dagger .
\]
Acting with \( \partial_t^2 + \Delta^2 \) on both sides of this relation yields
\[
(\partial_t^2 + \Delta^2)[\psi_- (0^+) - \psi_- (0^-)]
\]
Now we can insert into this relation the momentum decomposition of the field operator $\psi_-$

$$
\psi_-(x,t) = \int \frac{dk}{2\pi} e^{ik(t-x)} \begin{cases} a_k & \text{for} \ x < 0 \\ b_k & \text{for} \ x > 0 \end{cases}
$$

(9)

Because the dispersion relation is linear, $\omega = vk = k$, we can use $\omega$ as the momentum variable as well as the energy variable. Inserting Eq.(4) into Eq.(8) and using $\psi_-(0) = [\psi_+(0^+) + \psi_-(0^-)]/2$ results in

$$
E(b_\omega - a_\omega) = -i\beta_+(a_\omega + b_\omega) + i\gamma(a_{\omega}^\dagger + b_{\omega}^\dagger),
$$

(10)

where we introduced the following objects: $E = \Delta^2 - \omega^2$, $\beta_\omega = [(1-2\alpha)\Delta \pm \omega]/2$, $\gamma = \omega\sqrt{\alpha(1-\alpha)}$, and $\alpha = \gamma L^2/(\gamma L^2 + \gamma R^2)$ (the asymmetry parameter). From now on $\omega$, $\Delta$, the bias voltage $V$, and the temperature $T$ are all measured in units of $\Gamma = \gamma L^2 + \gamma R^2$. Considering in addition to Eq.(11) its complex conjugate for $-\omega$ we establish a relation between the amplitudes of the incoming ($a_\omega$) and transmitted ($b_\omega$) particle fluxes. The transmission coefficient can then be read off as follows:

$$
T(\omega) = \frac{4\gamma^2 E^2}{(E^2 + \beta_\omega^2)(E^2 + \beta_\omega^2) + 2\gamma^2(2E^2 + \beta_-\beta_+) + \gamma^4},
$$

(11)

This equation, accompanied by Eq.(3), provides all informations about the transport properties of the system and is the central result of this paper. The experimentally relevant quantity is the differential conductance $G = dI/dV$. At zero temperature, Eq.(3) considerably simplifies and, differentiating with respect to the bias voltage, one immediately finds that $G/G_0 = T(V)$. In the case when the couplings between the dot and the leads are perfectly symmetric and one of the chemical potentials matches $\Delta$, $G$ reaches the maximal value of $G_0$. This is a typical signature of the resonant tunnelling effect usually encountered in transport phenomena in double-barrier structures [12]. In fact, our system is a model for such a structure with one single state between the barriers.

The interplay between the LL’s enhancement of the backscattering at low temperatures (resulting in decreasing conductance) and the more standard Breit-Wigner physics emerging in the resonant tunnelling can be seen in Fig.1. As predicted in Refs.[3, 4], in the symmetric case $\alpha = 0.5$ and for $\Delta = 0$, the conductance saturates at low temperatures to its maximal value. In the presence of an asymmetry $G$ does not saturate any more and vanishes as a power–law towards $T = 0$ with the exponent 2. This value is equal to twice the density of states exponent $\nu$ of the LL with an open boundary: $\nu = 1/g - 1$ [3], which in our case is equal to 1. This fact indicates that in this regime the electrons are transferred through the system in a single stage process [3], so that the internal structure of the dot does not matter any more. Contrary to

$$
E(b_\omega - a_\omega) = -i\beta_+(a_\omega + b_\omega) + i\gamma(a_{\omega}^\dagger + b_{\omega}^\dagger),
$$

(10)

FIG. 2: The width of the resonant conductance peak as a function of temperature for different values of the asymmetry parameter $\alpha$.

Eq.(9) of NG, the high temperature ($T \gg 1$) evolution of the conductance follows the law $G/G_0 \sim 1/T$. The reason is that the problem maps onto a free-fermion one, for which the $1/T$ behaviour is inevitable. Note that, in the language of the original model, this corresponds to tunnelling of composite objects from one LL into the other.

Another interesting issue is the shape of the resonance peak, especially its width, $w(T)$, as a function of temperature, see Fig.2. At high temperatures it decreases linearly upon lowering $T$ no matter how strong are the interactions. For $T \ll 1$, however, the correlation effects become visible and the width $w(T)$ of the peak saturates at zero temperature unless the dot is symmetric. In the latter case $w(T)$ shrinks to zero with the exponent $1 - g$ predicted in Ref.[3]: $w(T) \sim T^{0.5}$.

It is in fact not difficult to evaluate the integral in Eq.(11) analytically. The general expression is complicated, so we shall only present here some particular cases. To begin with we observe that there is an intimate relation between our model at $\Delta = 0$, $\alpha = 1/2$ (resonant and symmetric case) and the $g = 1/2$ solution for the conductance through a single barrier ($G_s$) given in [3]. Indeed, evaluating (11) for the case in question, we find (in linear response)

$$
G_{\Delta=0}(T)/G_0 = \frac{1}{2\pi T} \psi'\left(\frac{1}{2} + \frac{1}{2\pi T}\right)
$$

(12)

where $\psi$ is the $\psi$-function. Comparing with Ref.[13] (see also [3]), we observe that $G_{\Delta=0}(T)/G_0 = 1 - G_s(T)/G_0$ if $T$ in $G_s$ is measured in units of the backscattering strength. One can easily show that an analogous relation continue to hold for the out–of–equilibrium current.

Furthermore, for the linear conductance when $\alpha = 1/2$ but $\Delta \neq 0 (|\Delta| < 1/2)$ we obtain

$$
G_{\Delta}(T)/G_0 = \frac{1}{2\pi T(\lambda_+^2 - \lambda_-^2)} \left(\lambda_+ \psi'\left(\frac{1}{2} + \frac{\lambda_+}{2\pi T}\right) - \lambda_- \psi'\left(\frac{1}{2} + \frac{\lambda_-}{2\pi T}\right)\right)
$$
the ratio of the resonance width and the backscattering.

For a strong small off-set of the resonance (if the two act independently), the asymmetry parameter is equivalent to $\alpha$ (and hence Q that was used in the preceding sections) is valid in the resonant but asymmetric case ($\Delta = 0$, $L = 0$). We show that the approximative scaling function $G_{\alpha=1/2}(X)$ is far more complicated than $G_{\alpha=1}(X) = 1/(1 + x^2)$ found by NG in weak coupling. Furthermore we observe from our analytic expressions that beyond $\Delta, T \ll 1$ there is no exact scaling. However, upon determining $\omega(T)$ numerically and plotting $\omega(T)/\Delta$ versus the dimensionless conductance $G/G_0$, we obtain an approximate numerical scaling as shown in Fig.3. The same scaling function holds in the resonant ($\Delta = 0$) but weakly asymmetric case, when $\alpha = 1/2$. In that situation $\alpha = 1/2$ substitutes $\Delta$ in the definition of $X$.

To summarise, we presented an explicit solution for the transport through a resonant level coupled to two LL leads. It turns out that for $g = 1/2$ the Hamiltonian of the system can be mapped onto one similar to the two-channel Kondo Hamiltonian in the Toulouse limit, solvable exactly. We obtained the full $I - V$ characteristics, which shows all the effects inherent to resonant tunnelling setups in LLs, including the scaling. Our solution confirms previous results obtained by means of the perturbation theory and goes beyond them. In future, it would be interesting to study deviations from $g = 1/2$ (in the spirit of Ref.[13]) and to investigate the effects of electron spin (and flavour).

The authors would like to thank H. Grabert and R. Egger for a valuable discussion. This work was supported by the Landesstiftung Baden-Württemberg gGmbH (Germany), by the EPSRC of the UK under grants GR/N19359 and GR/R70309, and by the EC network DIENOW.

[14] Strictly speaking $\psi(x = 0) = 0$, so we assume that the tunnelling takes place at the second last site of the corresponding lattice model, at $x = \pm a_0$. Also, we ignore the Klein factors as they can be absorbed into $\psi_{1/2}^{\pm}$. Disappearing from the analysis.
