We propose a high efficiency tomographic scheme to reconstruct an unknown quantum state of the qubits by using a series of quantum nondemolition (QND) measurements. The proposed QND measurements of the qubits are implemented by probing the stationary transmissions of the dispersively-coupled resonator. It is shown that only one kind of QND measurements is sufficient to determine all the diagonal elements of the density matrix of the detected quantum state. The remaining non-diagonal elements of the density matrix can be determined by other spectral measurements before transferring them to the diagonal locations using a series of unitary operations. Compared with the previous tomographic reconstructions based on the usual destructively-projective (DP) measurements (wherein one kind of such measurements could only determine one diagonal element of the density matrix), the present approach exhibits significantly high efficiency for $N$-qubit ($N > 1$). Specifically, our generic proposal is demonstrated by the experimental circuit-quantum-electrodynamics (circuit-QED) systems with a few Josephson charge qubits.

I. INTRODUCTION

The reconstruction of an unknown quantum state from a suitable set of measurements is called quantum tomography [1], which is a particularly important method in the study of quantum mechanics and its various applications. Since the characterization of the states is the central tasks in quantum-state engineering and controls, this technique is of great importance in the current quantum information processing. Recently, many theoretical analysis and experimental demonstrations have been devoted to implement the desirable quantum-state tomographies for, e.g., the polarization states of photons [2, 3], the electronic states of trapped ions [4], and the solid-state qubits [5], etc. However, all these tomographic constructions are based on the destructively-projective (DP) measurements, and thus are very operational-complicated. This is because that each kind of DP measurements, e.g., $P_k = |k\rangle \langle k|$, is required to be performed many times on many copies of the reconstructed state for determining just one of the elements (e.g., $|c_k|^2$ in the state $|\psi\rangle = \sum_k c_k |k\rangle$) in the density matrix $\rho = |\psi\rangle \langle \psi|$. 

Besides the usual DP measurements, quantum state could also be detected by other strategies, typically such as the so-called quantum nondemolition (QND) measurements. Basically, QND measurement is a nondestructive detection, as the measurement-induced back-action noises could be effectively suppressed by repeatedly hiding them in certain observables which are not of interests. The basic criteria for a QND measurement is that the repeated measurements of an observable $\hat{o}$ of the same system should yield the identical result. This means that the measured observable must be commutative with the Hamiltonian $H_{int}$ describing the interaction between the measured system and the detector, i.e., $[H_{int}, \hat{o}] = 0$. Historically, QND measurement is proposed to explore the fundamental limitations of measurements, and has been demonstrated in various branches of physics, such as in the detection of gravitational waves [6], quantum optics [7–9], telecommunications [10], and quantum control [11], etc. In recent years, the QND measurement has also been successfully applied to probe the atomic qubits in the cavity quantum electrodynamics (QED) [12, 13]. Furthermore, this technique was extensively used to the circuit QED systems [14–20] for nondestructively reading out the superconducting qubits. This QND measurement is implemented by measuring the transmission of the driven microwave signals through a transmission line resonator, which is dispersively coupled to the detected qubits. This is because that the detected qubits can cause sufficiently large state-dependent shifts of the resonator frequency. Thus by detecting the signals of the shifted frequency of the resonator, the qubit state will be read out. However, the QND measurements in the above works [14–20] are only utilized to effectively distinguish the different logic states of the detected qubit(s), which is (are) not prepared initially at their superposed state.

Motivated by the above experiments, recently we proposed a new scheme to nondestructively detect the superposition of these logic states by the QND measurements [21]. By taking into account of the full quantum correlations between the resonator and dispersively-coupled qubit(s), our proposal shows that each detected peak marks one of the logic states and the relative height of such a peak is related to its corresponding superposed probability. This means that one kind of the QND measurements can determine all the diagonal elements of the density matrix of the measured quantum state $\rho = |\psi\rangle \langle \psi|$. Similarly, the non-diagonal elements of $\rho$ could be determined...
by other kinds of QND measurements by performing the suitable unitary operations to transfer them into the measurable diagonal locations. Therefore, the proposed tomographic reconstructing approach is high efficient for $N$ ($N > 1$) qubits, as the number of the kinds of the QND measurements required is significantly decreased. For example, to tomographically reconstruct a two-qubit state, the proposed 6-kind QND measurements are sufficient. This is significantly simpler than the previous schemes (requiring 15-kind measurements) based on either the DPs [26] or the individual dispersive readouts of the logic states [20].

The paper is organized as follows: Sec. II gives our generic model of the transmissions of a driven resonator. In Sec. III, we provide a detailed analysis of the QND measurement of a single-qubit system by probing the transmissions of the driven resonator. Next, we show how to use these QND measurements to tomographically reconstruct an unknown single-qubit state in the experimental circuit-QED system. The extensions to the two-qubit case are given in Sec. IV, where the advantage of our proposal (compared with the previous approach based on the DP measurements) will be explicitly revealed. The possible generalization to the $N$-qubit situation and summarizations of our main results are finally given in Sec. V.

II. TRANSMISSION OF A DRIVEN EMPTY CAVITY

For the detection of the states of the qubits, we investigate the photon transmission of a driven resonator by studying the steady-state properties of the resonator-qubits dynamics. For generality, we consider a cavity-QED system consisting of $N$ qubits. The Hamiltonian reads

$$H = \hbar \omega_d \hat{a}^\dagger \hat{a} + \sum_{j=1}^{N} \left[ \frac{\hbar \omega_j}{2} \sigma_{z_j} + \hbar g_j (\sigma_{+j} \hat{a} + \sigma_{-j} \hat{a}^\dagger) \right],$$

where $a^{(1)}$ and $\sigma_{\pm j}$ are ladder operators for the photon field and the $j$th qubit respectively. Also, $\omega_d$ is the cavity frequency, $\omega_j$ the $j$th qubit transition frequency, and $g_j$ the coupling strength between the $j$th qubit and the resonator. Suppose that the cavity is coherently driven by

$$H_d = \hbar \epsilon (\hat{a}^\dagger e^{-i \omega_d t} + \hat{a} e^{i \omega_d t}),$$

where $\epsilon$ is the real amplitude and $\omega_d$ the frequency of the applied external driving.

Under the Born-Markov approximation, the dynamics of the whole system with the dissipations and dephasings is described by the following master equation [22]

$$\dot{\varrho}_N = -\frac{i}{\hbar} [H_N, \varrho_N] + \kappa \mathcal{D}[a] \varrho_N + \sum_{j=1}^{N} \gamma_{1j} \mathcal{D}[\sigma_{-j}] \varrho_N$$

$$+ \sum_{j=1}^{N} \gamma_{0j} \mathcal{D}[\sigma_{z_j}] \varrho_N,$$

$$H_N = H + H_d.$$  

Here, $\varrho_N$ is the density operator and the dissipation superoperator is defined by $\mathcal{D}[A] \varrho_N = A \varrho_N A^\dagger - A^\dagger A \varrho_N / 2 - \varrho_N A^\dagger A / 2$, which describes the effects of the environment on the system. The parameters of the last three terms in Eq. (3) correspond to photon decay rate $\kappa$, the $j$th qubit decay rate $\gamma_{1j}$, and the $j$th qubit pure dephasing rate $\gamma_{0j}$, respectively.

In what follows, we begin with the master equation (3) to calculate the frequency-dependent transmission of the cavity, which is proportional to the steady-state mean photon number $\langle \hat{a}^\dagger \hat{a} \rangle$ in the cavity. Technically, to satisfy the basic criteria for the desirable QND measurements of the $N$-qubit system, we assume that the conditions

$$0 < \frac{g_j}{\Delta_j} - \frac{\Delta_j}{\Delta_j' - \Delta_j} \ll 1, \ j \neq j' = 1, 2, \ldots, N,$$

should be satisfied for assuring the effective dispersive coupling $\sigma_{z_j} \hat{a}^\dagger \hat{a}$ between the $j$th qubit and the cavity. These conditions assure also that the inter-bit interactions are negligible. Above, $\Delta_j = \omega_j - \omega_r$, denotes the detuning between the $j$th qubit and the cavity, and $\Delta_j' = \omega_j - \omega_r'$ the detuning between the $j$th and $j'$th qubits.

For contrast, we first calculate the transmission spectrum of a driven empty cavity. The Hamiltonian of the simplified system reduces to ($\hbar = 1$ throughout the paper)

$$H_0 = \omega_r \hat{a}^\dagger \hat{a} + \epsilon (\hat{a}^\dagger e^{-i \omega_d t} + \hat{a} e^{i \omega_d t}).$$

After the time-dependent unitary transformation defined by the operator $R = \exp(-i \omega_d t \hat{a}^\dagger \hat{a})$, we get the effective Hamiltonian

$$\tilde{H}_0 = R^\dagger H_0 R - i R^\dagger \partial R / \partial t = -\Delta_{dr} \hat{a}^\dagger \hat{a} + \epsilon (\hat{a}^\dagger + \hat{a}),$$

where $\Delta_{dr} = \omega_d - \omega_r$ is the detuning of the cavity from the driving. Consequently, we get the master equation for such a driven empty cavity

$$\dot{\varrho}_0 = -i [\tilde{H}_0, \varrho_0] + \kappa (\hat{a} \varrho_0 \hat{a}^\dagger - \hat{a}^\dagger \hat{a} \varrho_0 / 2 - \varrho_0 \hat{a}^\dagger \hat{a} / 2),$$

where $\varrho_0$ is the density matrix of the empty cavity.

From the above master equation, one can easily obtain the equations of motion for the expectation values of the relevant operators, such as mean photon number inside the cavity $\langle \hat{a}^\dagger \hat{a} \rangle = T \varrho (\hat{a}^\dagger \hat{a} \varrho_0)$:

$$\frac{d\langle \hat{a}^\dagger \hat{a} \rangle}{dt} = -\kappa \langle \hat{a}^\dagger \hat{a} \rangle - 2\epsilon \text{Im}\langle \hat{a} \rangle,$$

with

$$\frac{d\langle \hat{a} \rangle}{dt} = (i \Delta_{dr} - \frac{\kappa}{2}) \langle \hat{a} \rangle - i \epsilon.$$ 

The steady-state solution of Eq. (8) gives

$$\frac{\langle \hat{a}^\dagger \hat{a} \rangle_{ss}}{\epsilon^2} = \frac{1}{(\omega_d - \omega_r)^2 + (\epsilon/2)^2}.$$  

Obviously, the transmission spectrum of an empty cavity, which is proportional to $\langle \hat{a}^\dagger \hat{a} \rangle$, is well-known Lorentzian: centered at $\omega_d = \omega_r$ with the half-width $\kappa$. Certainly, when $\omega_d$ does not sufficiently match the cavity frequency, no photon penetrates the cavity and thus no transmission is recorded.
III. TOMOGRAPHIC RECONSTRUCTION OF A SINGLE-QUBIT STATE BY QND MEASUREMENTS

A. Nondestructive detection of a single qubit by cavity transmissions

Now we investigate the case, in which a single qubit with transition frequency \( \omega_1 \) is dispersively coupled to the cavity mode. In the frame rotating at drive frequency \( \omega_d \) characterized by the transformation \( R \), the Hamiltonian of the system reads

\[
\hat{H}_1 = \frac{\tilde{\omega}_1}{2} \hat{\sigma}_z + (-\Delta_{dr} + \Gamma_1 \hat{\sigma}_z) \hat{a}^\dagger \hat{a} + \epsilon (\hat{a}^\dagger + \hat{a}), \tag{10}
\]

with \( \tilde{\omega}_1 = \omega_1 + \Gamma_1 \) and \( \Gamma_1 = g_1^2/\Delta_1 \).

Under the Born-Markov approximation, the master equation for the single-qubit plus the driven resonator is

\[
\dot{\hat{\rho}} = -i[H_1, \hat{\rho}] + \kappa \mathcal{D}[a] \hat{\rho} + \gamma_{1,1} \mathcal{D}[\sigma_{sz}] \hat{\rho}
\]

\[
+ \frac{\gamma_{1,1}}{2} \mathcal{D}[\sigma_z] \hat{\rho}, \tag{11}
\]

The desirable quantity \( \langle \hat{a}^\dagger \hat{a} \rangle \) can be determined by solving the following coupled equations of motion:

\[
\frac{d\langle \hat{a}^\dagger \hat{a} \rangle}{dt} = -\kappa \langle \hat{a}^\dagger \hat{a} \rangle - 2\epsilon \text{Im} \langle \hat{a} \rangle, \tag{12a}
\]

\[
\frac{d\langle \hat{a} \rangle}{dt} = (i\Delta_{dr} - \frac{\kappa}{2}) \langle \hat{a} \rangle - i\Gamma_1 \langle \hat{a} \hat{\sigma}_z \rangle - i\epsilon, \tag{12b}
\]

\[
\frac{d\langle \hat{a} \hat{\sigma}_z \rangle}{dt} = (i\Delta_{dr} - \frac{\kappa}{2} - \gamma_{1,1}) \langle \hat{a} \hat{\sigma}_z \rangle - (i\Gamma_1 + \gamma_{1,1}) \langle \hat{a} \rangle
\]

\[
- i\epsilon \langle \hat{\sigma}_z \rangle, \tag{12c}
\]

and

\[
\frac{d\langle \hat{\sigma}_z \rangle}{dt} = -\gamma_{1,1} \langle \hat{\sigma}_z \rangle + 1. \tag{12d}
\]

It is obvious that the additional measurement-induced dephasing rate \( \gamma_{1,1} \) does not influence the solution of the equations. As the decay \( \gamma_{1,1} \) of the qubit is significantly less than the decay rate \( \kappa \) of the driven cavity, the average of \( \hat{\sigma}_z \) could be safely assumed to be unchanged during the measurement. In fact, the characterized time of the detection is determined mainly by the decay of the cavity \( \kappa \). Such a quantity is about \( 2\pi \times 1.69 \text{ MHz} \) \([19]\), which is obviously larger than \( \gamma_{1,1} = 2\pi \times 0.02 \text{ MHz} \) \([16]\). Experimentally, the time interval of completing a single QND measurement is about \( T_{\text{r}} = 40\text{ ns} \) \([19]\), this is significantly shorter than the lifetime: \( T_1 \approx 7.3\mu\text{s} \) and the decoherence time: \( T_2 \approx 500\text{ ns} \) \([16]\). Therefore, during such a readout the decay of the qubit is negligible, i.e., \( \langle \hat{\sigma}_z(T_{\text{r}}) \rangle = \exp(-\gamma_{1,1} T_{\text{r}}) \langle \hat{\sigma}_z(0) \rangle + 1 \approx \langle \hat{\sigma}_z(0) \rangle \).

Under the steady-state condition, we obtain

\[
\langle \hat{a}^\dagger \hat{a} \rangle_{ss} = \frac{2}{\kappa} \times \left( \frac{\kappa}{4} + \frac{\gamma_{1,1}}{2} \right) \times \left( \epsilon \frac{\kappa}{4} + \gamma_{1,1} \frac{\kappa}{2} + \Gamma_1^2 - \Delta_{dr}^2 \right) + \left( \Delta_{dr} + \Gamma_1 \langle \hat{\sigma}_z(0) \rangle \right) \left( \epsilon \Delta_{dr} + \gamma_{1,1} \Delta_{dr} + \gamma_{1,1} \Gamma_1 \right)
\]

\[
\times \left[ \frac{\kappa}{4} + \frac{\gamma_{1,1}}{2} \right] + \Gamma_1^2 - \Delta_{dr}^2 \left( \Delta_{dr} + \Gamma_1 \langle \hat{\sigma}_z(0) \rangle \right) \left( \epsilon \Delta_{dr} + \gamma_{1,1} \Delta_{dr} + \gamma_{1,1} \Gamma_1 \right) \] \tag{13}

which is strongly related to the the initial state of qubit, thus the qubit state could be determined by the cavity transmission.

![Fig. 1: (Color online) Cavity transmission for the single-qubit states versus the probe detuning \( \omega_{d} - \omega_{s} \). Five cases of the qubit states for \( |\beta_{1}|^2 = 0, 0.2, 0.4, 0.5, \) and 1 are shown. For comparison, the empty cavity (EMC) transmission is also plotted in black line. The peak shifts by \(-\Gamma_1\) or \(\Gamma_1\) correspond to single logic state \(|0\rangle\) or \(|1\rangle\). For the superposition states, the double-peak relative heights (in contrast to the peak height of the empty cavity transmission) present clearly the superposed probabilities of the two logic states. Here, the parameters are selected as: \((\Gamma_1, \kappa, \gamma_{1,1}) = 2\pi \times (-7.38, 1.69, 0.02)\text{ MHz} \) \([16, 19]\).](image)

The measured cavity transmission (normalized to the peak height of the empty cavity transmission) versus the probe frequency detuning are plotted in Fig. 1. Generally, the qubit is assumed to be prepared initially in the state \(|\psi\rangle = \beta_0|0\rangle + \beta_1|1\rangle\). Obviously, when \( \beta_0 = 0 \), or 1, it reduces to the single logic state \(|0\rangle \) or \(|1\rangle \). Compared with the empty cavity transmission (plotted as the dark line in Fig. 1), one observes that qubit-resonator coupling leads to a right (left) shift of the single peak in the transmission spectrum by a quantity \(-\Gamma_1\) (\(\Gamma_1\)), which is dependent of the logic states for \(\langle \hat{\sigma}_z(0) \rangle \). Thus, the shifts of the peaks can be used to mark the logic states of the qubit. However, when the qubit is in the superposition of the two logic states, e.g., \(|\beta_{1}|^2 = 0.2, 0.4, \) and 0.5, respectively, we see that the situation is very different from the case for the single logic states. In this case, the spectrum shows two peaks whose locations coincide with that for the single logic states, but the relative heights of these two peaks correspond clearly to the
superposed probabilities, i.e., $|\beta_0|^2$ and $|\beta_1|^2$, respectively. This provides an effective approach to directly measure the superposed probabilities of a superposed state.

B. Tomographic reconstruction of a single-qubit state

Above investigation indicates that, partial information of the qubit state, i.e., the diagonal elements of the relevant density matrix, can be directly obtained by only one kind of the QND measurements. While, to extract the full information of an unknown qubit state, one should tomographically reconstruct all the elements of its density matrix. Basically, to completely define a $d$-dimensional density matrix $\rho$, one needs to determine $d^2 - 1$ real parameters. Therefore, to determine an unknown qubit state, the key point is to identify these parameters by virtue of the tomographic technique.

Now we demonstrate how to perform the tomographic construction of an arbitrary single-qubit state $|\psi\rangle_1 = \beta_0|0\rangle + \beta_1|1\rangle$, whose density matrix operator reads

$$\rho_1 = \begin{pmatrix} \rho_{00} & \rho_{01} \\ \rho_{10} & \rho_{11} \end{pmatrix}. \quad (14)$$

A more efficient and widely used technique is to parameterize the density matrix $\rho_1$ on a Bloch sphere [5],

$$\rho_1 = \frac{1}{2} (I + \sum_{i=x,y,z} r_i \sigma_i) = \frac{1}{2} \left( \begin{array}{cc} 1 + r_z & r_x - i r_y \\ r_x + i r_y & 1 - r_z \end{array} \right). \quad (15)$$

Here, $I$ denotes the identity matrix, $\sigma_j$ the Pauli matrices, and $r_i$ real parameters. Therefore, in order to determine the single-qubit state, we must identify the three components ($r_x, r_y, r_z$) of the Bloch vector $\vec{r}$. As discussed in the previous section, two diagonal elements $\rho_{00}$ and $\rho_{11}$ of the density matrix $\rho_1$ can be directly determined by the two measured occupation probabilities $|\beta_0|^2, |\beta_1|^2$ in the direct QND measurements. This means that the parameter $r_z$ can be determined by the relation $r_z = \rho_{00} - \rho_{11} = |\beta_0|^2 - |\beta_1|^2$. To obtain the other two parameters $r_x$ and $r_y$, we need to determine the non-diagonal elements. To this end, we perform the single-qubit operations: $U_{x_1} = \exp(i\pi \sigma_{z_1}/4)$ and $U_{y_1} = \exp(i\pi \sigma_{y_1}/4)$, to transfer them to the relevant diagonal locations, respectively. For example, after the operation $U_{x_1}$, the density matrix $\rho_1$ is changed to

$$\rho_1' = U_{x_1}\rho_1 U_{x_1}^\dagger = \frac{1}{2} \left( \begin{array}{cc} 1 - r_y & r_x - i r_z \\ r_x + i r_z & 1 + r_y \end{array} \right). \quad (16)$$

Now, performing another kind of QND measurements the parameters $|\beta_0'|^2$ and $|\beta_1'|^2$ can be measured. Consequently, the coefficient $r_y$ can be determined via the relation $r_y = |\beta_1'|^2 - |\beta_0'|^2$. Similarly, by performing the quantum operation $U_{y_1}$ on the original density matrix $\rho_1$, another new density matrix

$$\rho_1'' = U_{y_1}\rho_1 U_{y_1}^\dagger = \frac{1}{2} \left( \begin{array}{cc} 1 + r_y & -r_x - i r_z \\ -r_x + i r_z & 1 - r_y \end{array} \right). \quad (17)$$

can be obtained and the coefficient $r_x$ can be similarly determined. Note that here the number of the unitary operations required for implementing the quantum state tomography (based on the QND measurements) is the same as the previous approach (based on the usual DP measurements). Thus, for the single-qubit case the complexity of the present approach is the same as that in the previous one. Note that here, as the same as that in the previous approach based on the DP measurements, three kinds of QND measurements are still required for the present reconstructions. One is directly applied, another is applied after the $U_{x_1}$ operation, and the final one is applied after the $U_{y_1}$ operation, thus the efficiency is not enhanced.

The remaining task is to implement the single-qubit operations required above for transferring the non-diagonal elements to the diagonal locations. We work with a circuit-QED system wherein a superconducting charge qubit is coupled to the fundamental mode of a transmission line resonator [23]. Let the qubit work at its degeneracy point and neglect the fast oscillating terms under the rotating-wave approximation (RWA). Following Ref. [24], under one displacement transformation, the effective Hamiltonian of the resonator plus qubit system can be written as

$$\tilde{H} = -\Delta_{dr} \sigma_z + \frac{\Delta}{2} \sigma_{z_1} + g_1 (\sigma_{+1} + \sigma_{-1}) + \frac{\Omega}{2} \sigma_{x_1}, \quad (18)$$

with the detuning of the qubit transition frequency from the drive $\Delta_a = \omega_1 - \omega_d$ and the Rabi frequency $\Omega = 2g_1/(-\Delta_{dr})$. Next, supposing that this system works in the dispersive regime, i.e., $|g_1/\Delta| \ll 1$, after the transformation $U_1 = \exp\left[-\frac{i}{2} \sigma_{z_1} (\hat{a} \sigma_{-1} + \hat{a}^\dagger \sigma_{+1})/\Delta_1\right]$, then the above Hamiltonian becomes

$$H_x = -\Delta_{dr} \sigma_z + \frac{\Delta}{2} \sigma_{z_1} + \frac{\Omega}{2} \sigma_{x_1}, \quad (19)$$

First, if the condition $\Delta_a = 0$ is satisfied, then the Hamiltonian (19) produces a rotation of the qubit about the $x$ axis, i.e., $U_{x_1}$ could be generated by choosing the evolution time $t_x = \pi/(2\Omega)$. Second, if the driving is sufficiently detuned from the qubit and its amplitude is also sufficiently large enough, then another approximate Hamiltonian

$$H_z = -\Delta_{dr} \sigma_z + \frac{1}{2} (\Delta_a + \frac{\Omega^2}{\Delta_a}) \sigma_{z_1}, \quad (20)$$

can be obtained by further performing a transformations $U_z = \exp(i\pi \sigma_{z_1}/4) = \exp(i\pi \sigma_{y_1}/4) \exp(i\pi \sigma_{x_1}/4) \exp(i\pi \sigma_{y_1}/4) \exp(i\pi \sigma_{x_1}/4)$. It should be pointed out that the durations $t_{x}$ (or $t_y$) of the single-qubit operations required above for implementing the desirable tomographies is estimated as $\sim 100\text{ps}$ using the experimental parameters: $\epsilon \sim 2\pi \times 20\text{MHz}$ [18], and $\Delta_{dr} \sim \kappa/2$ [24]. This
is significantly less by at least two orders than the qubit decoherence time, which is measured as \( \sim 500\text{ns} \). Therefore, the required gate operations are accessible and the proposed tomographic reconstructions are experimentally feasible.

As an example, we assume that the three parameters \( r_x = 0.6, r_y = 0.5, r_z = 0.6 \) are obtained through the above reconstructions, then the reconstructed state \( \rho_1 \) can be written as \( \rho_1 = 0.8|0\rangle\langle 0| + (0.3 - 0.25i)|0\rangle\langle 1| + (0.3 + 0.25i)|1\rangle\langle 0| + 0.2|1\rangle\langle 1| \), whose real \( \rho_{ij}^{(R)} \) and imaginary \( \rho_{ij}^{(I)} \) parts (i,j=0,1) are graphically represented in Fig. 2.

![Graphical representations of the density matrix \( \rho_1 \) for a single-qubit state. The real \( \rho_{ij}^{(R)} \) and imaginary \( \rho_{ij}^{(I)} \) parts of the density matrix elements \( \rho_{ij} = \langle i|\rho|j \rangle \) (i,j=0,1) are plotted in (a) and (b), respectively.](image)

**IV. TOMOGRAPHIC RECONSTRUCTION OF A TWO-QUBIT STATE BY QND MEASUREMENTS**

#### A. Nondestructive detection of an unknown two-qubit state by cavity transmissions

We extend the above sing-qubit QND measurements to the two-qubit case. The transition frequencies of the two qubits are represented as \( \omega_1 \) and \( \omega_2 \), respectively. In the above dispersive condition (4) and in a framework rotating at \( \omega_d \), the effective Hamiltonian of the present complete system is

\[
H_2 = (-\Delta_d + \Gamma_1 \sigma_{z1} + \Gamma_2 \sigma_{z2}) a^\dagger a + \frac{\omega_1}{2} \sigma_{z1} + \frac{\omega_2}{2} \sigma_{z2} + \epsilon (a^\dagger + a),
\]

where \( \Gamma_j = g_j^2 / \Delta_j \) and \( \omega_j = \omega_j + \Gamma_j \), \( j = 1, 2 \).

Similarly, the relevant master equation reads

\[
\dot{\rho}_2 = -i[H_2, \rho_2] + \kappa D[a] \rho_2 + \sum_{j=1,2} \gamma_{1,j} D[\sigma_{-j}] \rho_2 + \sum_{j=1,2} \frac{\gamma_{0,j}}{2} D[\sigma_{zj}] \rho_2.
\]

and the equations of motion for the mean values of various expectable operators are

\[
\frac{d(\langle a^\dagger a \rangle)}{dt} = -\kappa (\langle a^\dagger a \rangle) - 2\epsilon \text{Im}(\langle a^\dagger a \rangle),
\]

\[
\frac{d(\langle a \rangle)}{dt} = (i\Delta_d - \frac{\kappa}{2}) \langle a \rangle - i\Gamma_1 (\langle a \sigma_{z1} \rangle - \langle \sigma_{z1} a \rangle) - i\Gamma_2 (\langle a \sigma_{z2} \rangle - \langle \sigma_{z2} a \rangle) - i\epsilon (\langle a \sigma_{z1} \rangle - \langle \sigma_{z1} a \rangle),
\]

\[
\frac{d(\langle a \sigma_{z1} \rangle)}{dt} = (i\Delta_d - \frac{\kappa}{2} - \gamma_{1,1}) \langle a \sigma_{z1} \rangle - (i\Gamma_1 + \gamma_{1,1}) \langle a \rangle - i\Gamma_2 \langle \sigma_{z1} a \rangle - i\epsilon \langle a \sigma_{z1} \rangle,
\]

\[
\frac{d(\langle a \sigma_{z2} \rangle)}{dt} = (i\Delta_d - \frac{\kappa}{2} - \gamma_{1,2}) \langle a \sigma_{z2} \rangle - (i\Gamma_2 + \gamma_{1,2}) \langle a \rangle - i\Gamma_1 \langle a \sigma_{z2} \rangle - i\epsilon \langle a \sigma_{z2} \rangle,
\]

\[
\frac{d(\langle a \sigma_{z1} \sigma_{z2} \rangle)}{dt} = (i\Delta_d - \frac{\kappa}{2} - \gamma_{1,1} - \gamma_{1,2}) \langle a \sigma_{z1} \sigma_{z2} \rangle - i\epsilon \langle a \sigma_{z1} \sigma_{z2} \rangle - (i\Gamma_1 + \gamma_{1,1}) \langle a \sigma_{z2} \rangle,
\]

\[
\frac{d(\langle \sigma_{z1} \rangle)}{dt} = -\gamma_{1,1} (\langle \sigma_{z1} \rangle + 1),
\]

\[
\frac{d(\langle \sigma_{z2} \rangle)}{dt} = -\gamma_{1,2} (\langle \sigma_{z2} \rangle + 1),
\]

\[
\frac{d(\langle \sigma_{z1} \sigma_{z2} \rangle)}{dt} = -\gamma_{1,1} (\langle \sigma_{z1} \sigma_{z2} \rangle - 1) - \gamma_{1,2} (\langle \sigma_{z2} \rangle + 1).
\]

Again, due to the relatively-long decoherence times of the qubits and their sufficiently short measured times, the additional measurement-induced dephasing and decay rates of the qubits are also unimportant. Thus, the expectable values of the qubit operators can still be regarded as unchanged, i.e., \( \langle \sigma_{z1}(t) \rangle \approx \langle \sigma_{z1}(0) \rangle \) and \( \langle \sigma_{z2}(t) \rangle \approx \langle \sigma_{z2}(0) \sigma_{z2}(0) \rangle \), during the desirable QND measurements. As a consequence, one can easily solve the above Eqs. (23a-e) and finally obtain the exact steady-state distribution of the intracavity photon number.
\[
\frac{\langle \hat{a}^{\dagger} \hat{a} \rangle_{ss}}{\epsilon^2} = \frac{2}{\kappa} \text{Re} \left\{ \frac{F(\sum_{j,j'} B_j D_j G_j + D_1 D_2) + B_1 B_2 G_{12}(D_1 + D_2) + \sum_{j,j'} E_j G_{j'}}{\sum_{j,j'} B_j E_j(D_j F + D_j A) - (B_1 E_1 - B_2 E_2)^2 - AD_1 D_2 F} \right\},
\]

where, \( A = i \Delta_{dr} - \frac{\xi}{2}, B_j = i \Gamma_j, D_j = i \Delta_{dr} - \frac{\xi}{2} - \gamma_{1,j}, E_j = i \Gamma_j + \gamma_{1,j}, F = i \Delta_{dr} - \frac{\xi}{2} - \gamma_{1,j} - \gamma_{1,j'}, G_j = \langle \sigma_{zj}(0) \rangle, \) and \( G_{12} = \langle \sigma_{z1}(0) \sigma_{z2}(0) \rangle. \)

Here, \( j, j' = 1, 2, j \neq j'. \) (24)

Also shows that, if the two-qubit is prepared initially as one of the Bell states: \( (|\alpha_1|^2, |\alpha_2|^2, |\alpha_3|^2, |\alpha_4|^2) = (0.5, 0, 0, 0.5) \), then the transmitted spectrum of the cavity reveals two peaks; their locations are respectively at the positions for the single states \(|00\rangle\) and \(|11\rangle\), but have the same relative heights. Moreover, for a more generic superposed state \( (|\alpha_1|^2, |\alpha_2|^2, |\alpha_3|^2, |\alpha_4|^2) = (0.1, 0.2, 0.3, 0.4) \) one can see that four peaks are exhibited simultaneously. The central positions of these peaks locate at the corresponding positions of single logic states \(|00\rangle, |01\rangle, |10\rangle, \) and \(|11\rangle\), respectively. The relative heights of them are 0.1, 0.2, 0.3, 0.4, respectively. Here, the relative heights of the peaks marking the states \(|00\rangle\) and \(|11\rangle\) are exactly equivalent to the superposed probabilities \( |\alpha_1|^2 \) and \( |\alpha_4|^2 \). However, the relative heights of the peaks marking the states \(|01\rangle\) and \(|10\rangle\) deviate from the corresponding superposed probabilities \( |\alpha_2|^2 \) and \( |\alpha_3|^2 \). This is because these two peaks are not well distinguished due to the contributions from these two logic states’ overlap. As a consequence, each peak is higher than the expected one, i.e., the superposed probability of the relevant logic state. While, such a situation does not exist for the \(|00\rangle\) and \(|11\rangle\) peaks (the relative heights of them equal to the expected ones), as they are separated sufficiently far from the others. In Fig. 3 (b) we modify the relevant parameters such as \( \Gamma_\alpha = 1.05 \Gamma_1 \) and \( \Gamma_\beta = 0.85 \Gamma_2 \). Then we find that each peak of the transmission of the cavity is well separated from the others, and thus its relative height is exactly equal to the expectable superposed probability of the corresponding logic state in the measured two-qubit state.

**B. High efficiency tomographic reconstruction of a two-qubit state**

The two-qubit state tomography is done in the same way as that for the single-qubit state. The only difference is that now there are 15 real parameters to be determined in the 4-dimensional density matrix operator \( \rho_2 \), and thus more operations are required to transfer the nondiagonal elements in \( \rho_2 \) to the diagonal locations. Generally, the 4-dimensional density matrix for a two-qubit state \( |\psi\rangle_2 = |\alpha_1|_00 + |\alpha_2|_01 + |\alpha_3|_10 + |\alpha_4|_{11} \) in a complete basis \( \{ |0\rangle_2 = |00\rangle, |1\rangle_2 = |01\rangle, |2\rangle_2 = |10\rangle, |3\rangle_2 = |11\rangle \} \) can be represented as

\[
\rho_2 = \begin{pmatrix}
\rho_{11} & \rho_{12} & \rho_{13} & \rho_{14} \\
\rho_{21} & \rho_{22} & \rho_{23} & \rho_{24} \\
\rho_{31} & \rho_{32} & \rho_{33} & \rho_{34} \\
\rho_{41} & \rho_{42} & \rho_{43} & \rho_{44}
\end{pmatrix},
\]

(25)

which can also be rewritten as \( \rho_2 = \tilde{\rho}_2/4 \) with [5]
\[ \rho_2 = \sum_{m,n=0,1,2,3} r_{mn} \sigma_{m1} \otimes \sigma_{n2} \]
\[ = \begin{pmatrix}
    r_{00} + r_{0z} + r_{zo} + r_{zz} & r_{0z} + r_{xz} - ir_{0y} - ir_{zy} & r_{0z} + r_{xz} - ir_{0y} - ir_{zy} & r_{0z} + r_{xz} - ir_{0y} - ir_{zy} \\
    r_{0z} + r_{xz} + ir_{0y} + ir_{zy} & r_{00} - r_{oz} + r_{zo} - r_{zz} & r_{00} - r_{oz} + r_{zo} - r_{zz} & r_{00} - r_{oz} + r_{zo} - r_{zz} \\
    r_{0z} + r_{xz} + ir_{0y} + ir_{zy} & r_{xx} + r_{yy} + ir_{xy} - ir_{yx} & r_{xx} + r_{yy} + ir_{xy} - ir_{yx} & r_{xx} + r_{yy} + ir_{xy} - ir_{yx} \\
    r_{0z} + r_{xz} - ir_{0y} + ir_{zy} & r_{xx} + r_{yy} - ir_{xy} + ir_{yx} & r_{xx} + r_{yy} - ir_{xy} + ir_{yx} & r_{xx} + r_{yy} - ir_{xy} + ir_{yx}
\end{pmatrix}. \]

(26)

Here, \( \sigma_{m=x,y,z} \) are the Pauli operators and \( \sigma_0 \) identity matrix, and what we want to determine is sixteen real parameters \( r_{mn} \). Note that the first and second subscripts of the matrix elements \( \rho_{ij} \) (i, j = 1, 2, 3, 4) in Eq. (25) and \( r_{mn} \) in Eq. (26) is labeled for the first and second qubits, respectively.

As in the above discussion, performing the QND measurements on the two-qubit state \( \rho_2 \) can directly determine all the four diagonal elements: \( \rho_{11}, \rho_{22}, \rho_{33} \) and \( \rho_{44} \), respectively, by the measured results \( | \alpha_1 |^2, | \alpha_2 |^2, | \alpha_3 |^2 \) and \( | \alpha_4 |^2 \). As a consequence, the parameters \( r_{00}, r_{0z}, r_{zo} \) and \( r_{zz} \) can be determined by

\[
\begin{align*}
    r_{00} &= | \alpha_1 |^2 + | \alpha_2 |^2 + | \alpha_3 |^2 + | \alpha_4 |^2 = 1, \\
    r_{0z} &= | \alpha_1 |^2 - | \alpha_2 |^2 + | \alpha_3 |^2 - | \alpha_4 |^2, \\
    r_{zo} &= | \alpha_1 |^2 + | \alpha_2 |^2 - | \alpha_3 |^2 - | \alpha_4 |^2, \\
    r_{zz} &= | \alpha_1 |^2 - | \alpha_2 |^2 - | \alpha_3 |^2 + | \alpha_4 |^2.
\end{align*}
\]

(27)

To determine the other 12 parameters, we need to perform certain unitary operations to transfer them to the diagonal locations for other QND measurements.

It is well-known that, arbitrary two-qubit operation assisted by arbitrary rotations of the single qubits generate an universal set of quantum gates. So the key to implement the above required operations for tomographies is to realize a two-qubit gate. Again, for the experimental circuit QED system with two superconducting charge qubits, such a gate could be implemented by using the so-called FLICFORQ protocol \cite{24}. In fact, if the cavity is driven by two external fields satisfying the sideband matching condition: \( \omega_{d_2} - \omega_{d_1} = \Omega_1 + \Omega_2 \), then an effective Hamiltonian

\[ \hat{H}_{\text{FF}} = \omega_i \hat{a}^\dagger \hat{a} + \frac{g_1 g_2 (\Delta'_1 + \Delta'_2)}{16 \Delta'_1 \Delta'_2} (\sigma_{y_1} \otimes \sigma_{y_2} + \sigma_{z_1} \otimes \sigma_{z_2}), \]

(28)

can be induced in a quadruply rotating framework. Here, \( \Delta'_j = \omega_j + 2 \Omega_j^2 / \Delta_{j,j'} \), \( \omega_j \) with \( \Omega_j = 2 g_j \sqrt{\epsilon_j} / (\omega_d - \omega_r) \), and \( \Delta_{j,j'} = \omega_j - \omega_{d_{j'}} \), \( j, j' = 1, 2, j \neq j' \). Obviously, the evolution under the above Hamiltonian with the duration, e.g., around \( \sim 100 \text{ps} \), for the experimental parameters \cite{24}, can produce a two-qubit operation:

\[ U_{\text{FF}} = \exp[i \pi (\sigma_{y_1} \otimes \sigma_{y_2} + \sigma_{z_1} \otimes \sigma_{z_2}) / 4]. \]

(29)

On the other hand, the typical single-qubit gates, e.g., \( U_{x_j}, U_{y_j}, \) and \( U_{z_j} \) (j = 1, 2) can be relatively easy to produce using the similar approaches presented in Sec. III. With such a two-qubit operation and these single-qubit gates, we show in Table I how to perform the desirable unitary operations for transferring the non-diagonal elements to the diagonal locations. For example, by performing a selected operational sequence \( W = U_{12}U_{y_1} \), on the original density matrix \( \rho_2 \), we have a new density matrix \( \rho'_2 = W \rho_2 W^\dagger \), and the new diagonal elements are

\[
\begin{align*}
    \rho'_{11} &= \frac{1}{4} (r_{00} + r_{xy} - r_{yz} + r_{zx}), \\
    \rho'_{22} &= \frac{1}{4} (r_{00} + r_{xy} + r_{yz} - r_{zx}), \\
    \rho'_{33} &= \frac{1}{4} (r_{00} - r_{xy} + r_{yz} + r_{zx}), \\
    \rho'_{44} &= \frac{1}{4} (r_{00} - r_{xy} - r_{yz} - r_{zx}).
\end{align*}
\]

(30)

Then, by the QND measurements the values of \( \rho'_1 \), \( \rho'_2 \), \( \rho'_3 \), and \( \rho'_4 \) are directly given. As a consequence, the desirable parameters \( r_{00}, r_{xy}, r_{yz} \) and \( r_{zx} \) can be obtained by the relations:

\[
\begin{align*}
    r_{00} &= | \alpha'_1 |^2 + | \alpha'_2 |^2 + | \alpha'_3 |^2 + | \alpha'_4 |^2 = 1, \\
    r_{xy} &= | \alpha'_1 |^2 + | \alpha'_2 |^2 - | \alpha'_3 |^2 - | \alpha'_4 |^2, \\
    r_{yz} &= - | \alpha'_1 |^2 + | \alpha'_2 |^2 + | \alpha'_3 |^2 - | \alpha'_4 |^2, \\
    r_{zx} &= | \alpha'_1 |^2 - | \alpha'_2 |^2 - | \alpha'_3 |^2 + | \alpha'_4 |^2. 
\end{align*}
\]

(31)

Similarly, other non-diagonal elements can also be determined. Clearly, here only six kinds of QND measurements are sufficient to tomographically reconstruct a two-qubit state. This is obviously simpler than the previous tomographies based on the usual DP measurements, wherein 15 kinds of measurements are probably required \cite{5,20}. Thus, the present tomographies is essentially high efficient.

After performing all the QND measurements listed in the table, a two-qubit state can be completely reconstructed. For example, a two-qubit state \( \rho_2 \) having the following representation:

\[
\begin{pmatrix}
    r_{00} & r_{0x} & r_{0y} & r_{0z} \\
    r_{x0} & r_{xx} & r_{xy} & r_{xz} \\
    r_{y0} & r_{yx} & r_{yy} & r_{yz} \\
    r_{z0} & r_{zx} & r_{zy} & r_{zz}
\end{pmatrix}
\]

(32)

which can be effectively reconstructed by these parameters
\[
\rho_2 = \begin{pmatrix}
\rho_{11} & \rho_{12} & \rho_{13} & \rho_{14} \\
\rho_{21} & \rho_{22} & \rho_{23} & \rho_{24} \\
\rho_{31} & \rho_{32} & \rho_{33} & \rho_{34} \\
\rho_{41} & \rho_{42} & \rho_{43} & \rho_{44}
\end{pmatrix} = \begin{pmatrix}
0.1 & 0.0313 - 0.0313i & 0.15 - 0.15i & -0.125i \\
0.0313 + 0.0313i & 0.2 & 0.125 & -0.15 + 0.15i \\
0.15 + 0.15i & 0.125 & 0.3 & -0.0313 + 0.0313i \\
-0.15 - 0.15i & -0.0313 + 0.0313i & 0.4
\end{pmatrix},
\]

TABLE I: The operational combinations before the QND measurements to determine the parameters for tomographically reconstructing a two-qubit state. The subscript "1(2)" of \( U \) is labeled for the operation of qubit 1(2).

| quantum operation \( W \) | determined parameters |
|--------------------------|-----------------------|
| no                       | \( \rho_{00}, \rho_{22}, \rho_{02}, \rho_{20} \) |
| \( U_{yF}U_{x1} \)      | \( \rho_{00}, \rho_{xy}, \rho_{yx}, \rho_{xx} \) |
| \( U_{yF}U_{y1} \)      | \( \rho_{00}, \rho_{yx}, \rho_{zy}, \rho_{yy} \) |
| \( U_{yF}U_{z1} \)      | \( \rho_{00}, \rho_{zy}, \rho_{yz}, \rho_{zz} \) |
| \( U_{y1}U_{z1}U_{yF} \) | \( \rho_{00}, \rho_{0y}, \rho_{y0}, \rho_{yy} \) |
| \( U_{y2}U_{zz}U_{yF} \) | \( \rho_{00}, \rho_{zy}, \rho_{yz}, \rho_{zz} \) |

FIG. 4: (Color online) Schematic representations of the density matrix \( \rho_2 \) for a two-qubit state. The real \( \rho_{ij}^{(R)} \) and imaginary \( \rho_{ij}^{(I)} \) parts \((i, j = 1, 2, 3, 4)\) of the density matrix elements in the complete bases are plotted in (a) and (b), respectively.

V. DISCUSSIONS AND CONCLUSIONS

Generally, the quantum state tomographic constructions demonstrated above can be extended for \( N \) (with \( N > 2 \)) qubits in a straightforward manner. This is because that the proposed QND measurements can be directly applied to determine all the diagonal elements of the arbitrary \( N \)-qubit state; the individual superposed logic states can be inferred from the relevant positions of the measured peaks, and the probabilities of the corresponding computational bases superposed in the measured state could be extracted from the relative heights of the peaks (when they separate sufficiently from the others). Moreover, all the required operations for the tomographic reconstructions can be implemented from the universal set of the logic gates demonstrated.

In summary, we have proposed a scheme to perform the quantum state tomographies by QND measurements. Differing from the usual tomographies based on the DP measurements, here the QND measurements are utilized. Since all the diagonal elements of the density matrix of an unknown quantum state can be simultaneously determined by a single kind of QND measurements, the efficiency of the present tomographic reconstruction is definitely better for more qubits. Specifically, our proposal is demonstrated with the current circuit QED setup with a few charge qubits, and could be generalized to other systems, in principle.
