Large-scale preparation of nanoporous TiO₂ film on titanium substrate with improved photoelectrochemical performance

Beihui Tan, Yue Zhang and Mingce Long*

Abstract

Fabrication of three-dimensional TiO₂ films on Ti substrates is one important strategy to obtain efficient electrodes for energy conversion and environmental applications. In this work, we found that hierarchical porous TiO₂ film can be prepared by treating H₂O₂ pre-oxidized Ti substrate in TiCl₃ solution followed by calcinations. The formation process is a combination of the corrosion of Ti substrate and the oxidation hydrolysis of TiCl₃. According to the characterizations by scanning electron microscopy (SEM), X-ray diffraction (XRD), and diffuse reflectance spectroscopy (DRS), the anatase phase TiO₂ films show porous morphology with the smallest diameter of 20 nm and possess enhanced optical absorption properties. Using the porous film as a working electrode, we found that it displays efficient activity for photoelectrocatalytic decolorization of rhodamine B (RhB) and photocurrent generation, with a photocurrent density as high as 1.2 mA/cm². It represents a potential method to fabricate large-area nanoporous TiO₂ film on Ti substrate due to the scalability of such chemical oxidation process.

Keywords: Nanoporous TiO₂ film; Titanium substrate; Photocurrent; Photoelectrocatalysis

Background

In recent years, TiO₂ has been widely studied and applied in diverse fields, such as photocatalysis, dye-sensitized solar cell, self-cleaning surface, sensor, and biomedicine [1-6]. It is well known that TiO₂ nanoparticles have the potential to remove recalcitrant organic pollutants in wastewater. However, it is prerequisite to produce immobilized TiO₂ photocatalysts with highly efficient activity by scale-up methods. Recently, considerable efforts have been taken to use metallic titanium as the precursor to develop three-dimensional TiO₂ films with controllable ordered morphologies, such as nanotubes [7], nanorods [8], nanowires [9], and nanopores [10]. The in situ-generated TiO₂ films over titanium substrates possess such advantages as stable with low carbon residual, excellent mechanical strength, and well electron conductivity, which make them suitable to be used as electrodes for photoelectrochemical-related applications [6,11]. Although a well-defined structural nanotube or nanoporous TiO₂ film on metallic Ti can be synthesized by an anodic method [6,7,10-13], it is still a big challenge to scale up the production of such TiO₂ film due to the limitation of electrochemical reactor and the high energy consumption. Chemical oxidation methods by treating titanium substrates in oxidation solutions are more scalable for various applications. By soaking titanium substrates in H₂O₂ solution followed with calcinations, titania nanorod or nanoflower films can be obtained [8,14]. However, the film always displays discontinuous structure with many cracks, and its thickness is less than 1 μm [8,15]. Both of these would result in a low photoelectrochemical performance. With the addition of concentrated NaOH in the H₂O₂ solution, a porous nanowire TiO₂ film can be achieved after an ionic exchange with protons and subsequent calcinations [9]. Employing NaOH and organic solvent as the oxidation solution and elevating the treating temperature, Ti substrate would completely transform into free-standing TiO₂ nanowire membranes [16]. However, the disappearance of Ti substrate makes this membrane impossible to serve as an electrode.

Compared to titanium alkoxides or TiCl₄, there are much fewer reports on the synthesis of TiO₂ nanostructure...
with the precursor of TiCl₃. Normally, anatase TiO₂ film can be fabricated via the anodic oxidation hydrolysis of TiCl₃ solution [17,18]. Recently, Hosono et al. synthesized rectangular parallelepiped rutil TiO₂ films by hydrothermally treating TiCl₃ solution with the addition of a high concentration of NaCl [19], and Feng et al. developed TiO₂ nanorod films with switchable superhydrophobicity/superhydrophilicity transition properties via a similar method [20]. Moreover, a hierarchically branched TiO₂ nanorod film with efficient photon-to-current conversion efficiency can be achieved by treating the nanorod TiO₂ film in TiCl₃ solution [21]. However, all of these nanostructural TiO₂ films from TiCl₃ solution were grown over glass or alumina substrates. Fabricating nanostructural TiO₂ films over metallic Ti substrates is a promising way to providing high-performance photoresponsive electrodes for photoelectrochemical applications. The obstacle for starting from Ti substrates and TiCl₃ solution must be the corrosion of metallic Ti at high temperatures in the HCl solution, which is one of the components in TiCl₃ solution. However, the corrosion could also be controlled and utilized for the formation of porous structures. According to reports, the general method to prepare nanoporous TiO₂ film on Ti substrate is through anodic oxidation and post-sonication [10,12]. In this contribution, we proposed a facile way to fabricate nanoporous TiO₂ films by post-treating the H₂O₂-oxidized TiO₂ film in a TiCl₃ solution. The as-prepared nanoporous TiO₂ film display homogeneous porous structure with enhanced optical adsorption property and photoelectrocatalytic performance, which indicates that the film is promising in the applications of water purification and photoelectrochemical devices.

Methods
Cleansed Ti plates (99.5% in purity, Baoji Ronghao Ti Co. Ltd., Shanxi, China) with sizes of 1.5 × 1.5 cm² were pickled in a 5 wt% oxalic acid solution at 100°C for 2 h, followed by rinsing with deionized water and drying in an air stream. The nanoporous TiO₂ film was prepared by a two-step oxidation procedure. Briefly, the pretreated Ti plate was firstly soaked in a 15 mL 20 wt% H₂O₂ solution in a tightly closed bottle, which was maintained at 80°C for 12 h. The treated Ti plate was rinsed gently with deionized water and dried. Then, it was immersed in a 10 mL TiCl₃ solution (0.15 wt%) at 80°C for 2 h. Finally, the film was cleaned, dried, and calcined at 450°C for 2 h. The obtained nanoporous TiO₂ film was designed as NP-TiO₂. Two control samples were synthesized, including the one designed as TiO₂-1, which was obtained by directly calcining the cleansed Ti plate, and the other named as TiO₂-2, which was prepared by one-step treatment of the Ti plate in a TiCl₃ solution.

The surface morphology of TiO₂ films was observed using a field emission scanning electron microscope (SEM; Zeiss Ultra 55, Oberkochen, Germany). The crystal phases were analyzed using a powder X-ray diffractometer (XRD; D8 Advance, Bruker, Ettlingen, Germany) with Cu Kα radiation, operated at 40 kV and 36 mA (λ = 0.154056 nm). UV-vis diffuse reflectance spectra (DRS) were recorded on a Lambda 950 UV/Vis spectrophotometer (PerkinElmer Instrument Co. Ltd., Waltham, MA, USA) and converted from reflection to absorption by the Kubelka-Munk method.

Photoelectrochemical test systems were composed of a CHI 600D electrochemistry potentiostat, a 500-W xenon lamp, and a homemade three-electrode cell using as-prepared TiO₂ films, platinum wire, and a Ag/AgCl as the working electrode, counter electrode, and reference electrode, respectively. A 0.5 M Na₂SO₄ solution purged with nitrogen was used as electrolyte for all of the measurements.

The photocatalytic or photoelectrocatalytic degradation of rhodamine B (RhB) over the NP-TiO₂ film was carried out in a quartz glass cuvette containing 20 mL of RhB solution (C₂₈H₃₁ClN₂O₃, initial concentration 5 mg/L). The pH of the solution was buffered to 7.0 by 0.1 M phosphate. The solution was stirred continuously by a magnetic stirrer. Photoelectrocatalytic reaction was performed in a three-electrode system with a 0.5-V anodic bias. The exposed area of the electrodes under illumination was 1.5 cm². Concentration of RhB was measured by spectrometer at the wavelength of 554 nm.

Results and discussion
Figure 1 shows the surface morphologies of films obtained by different procedures. The control sample TiO₂-1 is obtained by the calcination of the pickled Ti plate at 450°C for 2 h. The typical coarse surface formed from the corrosion of Ti plate in oxalic solution can be observed (Figure 1A,B). By oxidation at a high temperature, the surface layer of titanium plate transformed into TiO₂. However, the surface morphology shows negligible change. The film of TiO₂-2, which is synthesized by directly treating the cleansed and pickled Ti plate in TiCl₃ solution, displays smoother surface with no observable nanostructure (Figure 1C,D). Moreover, there are discernible TiO₂ particles dispersing over the surface. It suggests that in the TiCl₃ solution the surface morphology of Ti plate has been modified after dissolution, precipitation and deposition processes. By treating the H₂O₂ pre-oxidized Ti plate in TiCl₃, the film displays a large-scale irregular porous structure, as shown in Figure 1E,F. Moreover, the appearance of NP-TiO₂ film is red color (as inset in Figure 1F), which is different from the normal appearance of most anodic TiO₂ nanorod or nanotube films [22]. The pores are in the sizes of 50 to
100 nm on the surface and about 20 nm inside; the walls of the pores are in the sizes of 10 nm and show continuous connections. Such hierarchical porous structure contributes to a higher surface area of the TiO\(_2\) film. Normally, titanium suffers from corrosion in the hot HCl solution, and the corrosion rate depends on the temperature and the concentration of acid. Without pre-oxidation, the surface layer of Ti plate is exposed to be etched and dissolved in the reaction solution at a medium temperature. Simultaneously, the TiOH\(^{2+}\) and Ti(IV) polymer generated by the hydrolysis of TiCl\(_3\) would precipitate and deposit over the surface (Equations 1 and 2) so as to retard the corrosion of Ti plate and avoid the completed dissolution of Ti plate [17,19]. For the NP-TiO\(_2\) film, after the first step of oxidation in H\(_2\)O\(_2\) solution, peroxy complexes coordinated to Ti(IV) have already formed, which cover most parts of the surface and be ready for further growth by the interaction with the oxidation hydrolytic products of TiCl\(_3\). However, it is also possible that HCl solution enters the interstitial of the TiO\(_2\) nanorod film and induces etching of the substrate Ti. At the experimental temperature, the dissolution of Ti is slow. With the reorganization of Ti(IV) polymer precursor, a porous structure forms over the Ti plate, as shown in Figure 1F.

\[
\text{Ti}^{3+} + \text{H}_2\text{O} \rightleftharpoons \text{TiOH}^{2+} + \text{H}^+ \quad (1)
\]

\[
\text{TiOH}^{2+} + \text{O}_2 \rightarrow \text{Ti(IV) oxo species}
+ \text{O}_2^- \rightarrow \text{TiO}_2 \quad (2)
\]

Figure 2A is the XRD pattern of NP-TiO\(_2\) film. The strong diffraction peaks at about 35.2°, 38.7°, 40.4°, 53.3°, and 63.5° can be assigned to the metallic Ti (JCPDS 44-1294). At the same time, the peak at 25.3° corresponds to the (101) plane of anatase phase TiO\(_2\) (JCPDS 83-2243). Diffraction peaks of rutile or brookite cannot be found, indicating that the titania film is composed of exclusively anatase. DRS spectra were measured to analyze the optical absorption properties of the films, as shown in Figure 2B. There is almost no optical adsorption for the TiO\(_2\)-1 film, indicating that only a very thin layer of metallic Ti transforms into TiO\(_2\) after the calcination of Ti plate, and this contributes a poor photoresponse performance. TiO\(_2\)-2 film displays a typical semiconductor optical absorption with the adsorption edge at about 380 nm, corresponding to the band gap of
anatase TiO$_2$. However, the absorption is relatively low, indicating that only few of TiO$_2$ nanoparticles deposit over the surface of TiO$_2$-2 film. The strong optical absorption appearing below 400 nm for NP-TiO$_2$ film suggests a full growth of TiO$_2$ layer over the Ti plate. Moreover, several adsorption bands centered at about 480, 560, and 690 nm can be observed in the spectrum of NP-TiO$_2$ film. They possibly originated from the periodic irregular nanoporous structure. Such nanoporous structure is favorable to increase the photoresponsive performance, because the incident light that entered the porous structure would extend the interaction of light with TiO$_2$ and result in an enhanced absorption performance, which can be observed in other nanotube or photonic crystal structural TiO$_2$ films [22,23].

Using TiO$_2$ films as the working electrodes in a three-electrode system, photocurrents under irradiation with full spectrum of light source were measured and compared, as shown in Figure 3. From the current transients (inset in Figure 3), all films show anodic photocurrents upon illumination, corresponding to the n-type photoresponse of TiO$_2$. For TiO$_2$-1 film, the initial anodic photocurrent spike is very strong and subsequently decays quickly. Simultaneously, a cathodic overshoot appears immediately when the light is switched off. The anodic current spike and cathodic overshoot are occasionally observed in many cases, and which is generally regarded as the indication of the surface recombination of photogenerated charges [24-26]. A decay of anodic current immediately after the initial rise of the signal when the light is switched on is attributed to photogenerated electron transfer to the holes trapped at the surface states or the intermediates which originated from the reaction of holes at the semiconductor surface. With the accumulation of the intermediates, the electrons are trapped by the surface states, resulting in an anodic current spike. Owing to the same reason, the intermediates or trapped holes would induce a cathodic overshoot when switching off the light. The obvious
strong spike for the illuminated TiO$_2$-1 film suggests the slow consumption of holes and the corresponding oxidation process, which is related to the activity of the surface TiO$_2$ layer. The poor crystallinity, large TiO$_2$ particles, and the small amount of TiO$_2$ in the directly oxidized film would result in the poor photoelectrochemical performance. However, the transient of NP-TiO$_2$ film is different, displaying much smaller anodic current spike and more stable photocurrent. The photocurrent density is calculated as the difference of the current density upon illumination at the center time and in the dark, which is shown as a graph in Figure 3. NP-TiO$_2$ film possesses the highest photocurrent density, which is about 1.2 mA/cm$^2$, significantly higher than the corresponding TiO$_2$-1 and TiO$_2$-2 films. The efficient photoelectrochemical performance can be attributed to the porous structure of NP-TiO$_2$ film, in which the interaction time between TiO$_2$ and light would be increased due to the trapped photons inside the pores, corresponding to its enhanced optical absorption.

The performance of the NP-TiO$_2$ film was further tested by photoelectrocatalytic degradation of RhB solutions. The decolorization of RhB by photolysis is low, only 5.2% reduction observed after 2 h of irradiation (Figure 4). Without an applied bias, by illuminating the solution with the NP-TiO$_2$ film, the decolorization efficiency only improved to about 11%. This low photocatalytic efficiency of the film could be attributed to the too small active area of the film and the phosphate in the buffered solution, which is regarded as the scavenger of radicals [27]. However, with a bias of 0.5 V vs. Ag/AgCl, the decolorization of RhB has been significantly improved, about 52.8% decolorization of RhB solution after 2 h of irradiation. Photoelectrocatalysis is a combination of photocatalysis and electrooxidation using the semiconductor films. By this method, an anodic bias on NP-TiO$_2$ film is used to drive photogenerated electrons and holes moving toward different direction, so as to suppress the recombination and promote the organic degradation [11,28]. Moreover, besides the improved optical absorption, the porous structure also contributes to a short diffusion path for RhB molecules to the active surface area. Therefore the NP-TiO$_2$ film displays efficient photoelectrocatalytic activity for organic degradation. It can be expected that the chemical oxidation method for NP-TiO$_2$ films is scalable for practical applications. With a larger active area, the NP-TiO$_2$ film is potential to be used as an efficient electrode for energy conversion and organic pollutant removal.

Conclusions

A nanoporous TiO$_2$ film on Ti substrate was synthesized by treating the initially H$_2$O$_2$-oxidized Ti plate in hot TiCl$_3$ solution and followed by calcinations. The pre-oxidation in H$_2$O$_2$ solution is necessary to form such porous structure, indicating that the formation process is a combination of the corrosion of Ti substrate and the oxidation hydrolysis of TiCl$_3$. The film possesses exclusively anatase phase and hierarchical porous morphology, with the diameter of the inside pores as small as 20 nm. The porous TiO$_2$ film displays enhanced optical absorption, photocurrent generation, and efficient photoelectrocatalytic activity for RhB decolorization. The generated photocurrent density can reach as high as 1.2 mA/cm$^2$. The chemical oxidation method for the nanoporous TiO$_2$ film is possible to be scaled up and developed into a strategy to provide efficient TiO$_2$ electrodes for diverse applications.
