Subduction zone fluids and arc magmas conducted by lithospheric deformed regions beneath the central Andes

E. Contreras-Reyes1,2, J. P. Bello-González3, K. Slezak1, B. Potin1, D. Comte1, A. Maksymowicz1, J. A. Ruiz1, A. Osses4 & S. Ruiz1

Dehydration of the oceanic subducting slab promotes the formation of magmatic arcs, intra-slab intermediate-depth seismicity, and hydration of the overlying mantle wedge. However, the complex permeability structure of the overriding plate controls the magma and fluid migration and their accumulation at shallower depths. In this regard, mapping the inner structure of the overriding crust and mantle is crucial to understand the magmatic and hydrological processes in subduction zones.

We integrate 3-D P-wave, $V_P/V_S$, and electrical resistivity tomographic models of the northern Chilean subduction zone to map the magmatic and fluids derived from the subducting oceanic Nazca plate. Results show a continental crust relatively thick (50–65 km) characterized by a lower zone of high $V_P$ values (7.2–7.6 km/s), which is interpreted as the presence of plutonic rocks. The mantle lithospheric wedge is weakly hydrated ($V_P/V_S=1.75–1.8$) while the forearc continental crust is traversed by regions of reduced electrical resistivity values ($<10^2 \Omega m$) interpreted as zones of relatively high permeability/fracturing and fluid content. These regions spatially correlate with upper plate trans-lithospheric deformation zones. Ascending melts accumulate preferentially in the back-arc, whereas hydrothermal systems form trenchward of the volcanic arc. The results highlight the complex permeability structure of the upper South American plate.

The release of fluids in subduction zones is an important process controlling earthquakes both in the subducting/oceanic plate and in the seismogenic megathrust fault zone1,2. Dehydration reactions depend on the pressure-temperature conditions of the subducting slab and might trigger mantle wedge serpentinization (20–40 km depth3,4), intraplate seismic activity (>60–80 km depth6,7), and arc magmatism (> 100 km depth8,9). Several geophysical studies suggest that hydration of the oceanic plate is most vigorous at the trench-outer rise prior to subduction, where extensional bending-related faulting affects the hydrogeology of the oceanic crust and mantle6,8,9. A larger amount of seawater is more likely to be stored in subduction zones composed by an old and cold oceanic plate that hosts a thicker brittle faulting regime in the upper part of the oceanic lithosphere6,9,10. In fact, old and cold oceanic lithosphere usually present well developed bending-related faults of deep penetration (> 6 km below seafloor) and a large population of horst-and-grabens structures of high vertical offset6,7,12. Classical examples include Marianas13, Kuril14, Tonga15, and northern Chile2.

As the temperature and pressure increases with depth during subduction of a hydrated oceanic plate, metamorphic dehydration reactions take place3,6. For instance, dewatering of subducting sediments and oceanic crust at depths between 30 and 70 km has been invoked to explain mantle wedge serpentinization3,10,16,17. Metamorphic dehydration processes of the subducting oceanic crust increase pore pressure and decrease effective confining pressure, thereby promoting intra-crustal seismicity3,10,16 (60-80 km depth). At depths larger than 100 km, the subducting upper lithospheric mantle dehydrates lowering the melting temperature of the overlying mantle and causing partial melting3,16,17. This process leads to the formation of magma that eventually ascends to form an arc of volcanoes and/or accumulates within the overriding plate to form plutonic bodies8,18. Depending on the permeability and inner structure of the overriding crust and mantle, the ascending melts would favorably accumulate

in deformation zones dominated by a stress regime of tension. Hydraulic fracturing can also lead secondary permeability generation by exsolved hydrothermal fluids from the ascent and depressurization of magma.

The Central Volcanic Zone (CVZ) of the Andes is characterized by the subduction of the oceanic Nazca plate beneath the upper South American Plate (SAP) at 14°-28°S. Here, eruptions of caldera scale complexes resulted in immense Late Miocene to Pliocene ignimbrite deposits overlying basaltic and andesitic volcanic rocks, particularly related to the Altiplano-Puna volcanic complex. Today, the active volcanic segment extended between 16° and 28°S and is characterized by an average angle of subduction of 30° at 100 km depth, whereas north of 14°S and south of 28°S, the active volcanism vanishes, correlating with sub-horizontal subduction (<10°). Seismic data show that the continental crust under the Andean orogen is extremely thick (60–70 km in average) below the Precordillera and volcanic arc, and it is 60–65 km thick below the Puna/backarc. The very thick crust below the CVZ is believed to be caused by the combination of long-term crustal shortening and magmatic underplating, with more crustal shortening in the Precordillera and more magmatic underplating below the volcanic arc. Regarding the crustal shortening contribution to crustal growth, geochemical evidence shows an increase in crustal thickness during the Cretaceous followed by a delamination episode. Crustal thickness increases again during the last shortening phase occurred during the last 10–22 Myr.

The western flank of the volcanic arc is limited by the Domeyko Fault Zone System (DFZS) that was an intra-crustal strike slip fault zone system aligned with the magmatic arc axis during the late Eocene and Early Oligocene. Later, the DFZS experienced tectonic inversion evolving from uplift to thrusting facilitating the formation of the Salar de Atacama Basin. On the other hand, the arcward flank of the Coastal Cordillera (a paleomagmatic arc) is delimited by the Atacama Fault Zone System (AFZS), which orients parallel to the trench axis extending for more than 1100 km along the margin (Fig. 1).

In this study, we map the structure of the continental crust and mantle wedge in order to explore the presence of fluids and/or magmatic/intrusive bodies, and how they spatially correlate with intra-crustal fault systems in the northern Chilean subduction zone. We use a compilation of recently published 3-D P-wave ($V_p$) and P-to S-wave ratios ($V_p/V_s$) models obtained from regional earthquake tomography, complemented with 3-D electrical resistivity ($\rho$) models to study the crustal and upper mantle structure of the SAP beneath the CVZ (Fig. 1). We discuss the processes related to the ascending magma upwellings through a thick and faulted overriding continental crust and their implications for arc volcanism.

**Hydration of the oceanic Nazca plate prior to subduction**

Offshore northern Chile, the Nazca plate is 40-50 Myr old, and is characterized by a pronounced forebulge or outer rise prior to subduction in the deep trench. In addition, gravity, active and natural seismic studies show that the oceanic crust and upper mantle of the Nazca plate are pervasively fractured and hydrated at the outer rise region caused by plate bending. Yield strength envelope models predict that the brittle portion for an oceanic lithosphere 40–50 Myr old is 30–40 km thick under tensile stresses, which is about twice thicker...
than an oceanic lithosphere 10–15 Myr old\textsuperscript{39–41}. Thus, the relatively old and cold Nazca plate offshore northern Chile is capable to store a large amount of water when the yield strength of the lithosphere is exceeded and the upper plate is subsequently hydrated. In this regard, flexural models show a systematic reduction in the elastic properties of the Nazca plate likely caused by bending-related faulting in the outer rise region offshore northern Chile\textsuperscript{45,39,40}. Thereby, the possibly large amount of seawater stored in the upper Nazca plate has a considerable potential to affect the hydrology, rheology, and magmatism of the overlying SAP via dehydration reactions and partial melting as we discuss in the next sections.

The upper continental South American plate

**Geological setting.** The locations of the main morpho-structural units are shown in Fig. 1, which are:

1. The Coastal Cordillera (the paleo-magmatic arc) composed by Palaeozoic intrusive, Jurassic-Triassic intrusive, sedimentary and volcanic rocks.
2. The Central Depression (Longitudinal Valley) composed by volcanic and plutonic rocks that underlies younger forearc basins.
3. The Pre-cordillera (Cordillera de Domeyko) is composed by Mesozoic sediments that are ponded unconformably upon metamorphic basement and plutonic rocks.
4. The Salar de Atacama Basin (SAB) is part of the Pre-Andean Depression formed in the early Late Cretaceous\textsuperscript{45}.

**The Atacama fault zone system.** The AFZS is a strike slip structure that has undergone periods of inactivity and reactivation since the early Jurassic and controlled the arc magmatism in that time (the present Coastal Cordillera). In the Coastal Cordillera, the magmatism occurred in three primary pulses: a minor Late Jurassic event and reactivation since the early Jurassic and controlled the arc magmatism in that time (the present Coastal Cordillera). In the Coastal Cordillera, the magmatism occurred in three primary pulses: a minor Late Jurassic pulse (185–175 Ma), broad Early Cretaceous pulse from 150–120 Ma, and a younger pulse at 120–105 Ma\textsuperscript{46}. Fault scarp and surface ruptures indicate different degrees of reactivation of the AFZS up to present that most likely roots into the subduction zone interface indicating the interplay between the AFZS and the subduction interface\textsuperscript{47,48}. Moreover, fault activity is expressed as a group of fault-bend fold scarps whose orientation defines three main domains: WNW-ESE, N-S and NW-SE\textsuperscript{49}. These domains were coevally active during the Neogene, accommodating the greatest amount of deformation during the Miocene, continuing their activity during the Pliocene and Lower Pleistocene. The AFZS morphologies and secondary structures suggest that the mechanisms responsible for the deformation are still active\textsuperscript{49}.

**The Domeyko fault zone system.** The DFZS is a Cenozoic first order structure characterized by a first pulse of Palaeoene-Early Eocene deformation characterized by dextral transpression. A second deformation pulse during the Late Eocene-early Oligocene caused relaxation of convergent stresses that reversed the sense of movement on the DFZS and generated transtensional volumes within the zone of structural intersection. During the Neogene-Quaternary the conjugate sinistral NW-SE and dextral SW-NE faults have been also activated\textsuperscript{50}. Neotectonic activity during the Plio-Quaternary period in the western flank of the Domeyko Cordillera has also been observed by Audin et al., (2003)\textsuperscript{51} related to fault scarps that cut through alluvial deposits and are distributed parallel to the DFZS.

**Geophysical results and interpretation**

**Seismic constraints.** The extracted cross sections for the \(V_p\) and \(V_p/V_s\) models\textsuperscript{52} are shown in Fig. 2, whereas seismicity was taken from the results of Comte et al., (2016)\textsuperscript{53} who relocate hypocenters using local seismic networks in northern Chile. Most of the seismicity occurred in the oceanic Nazca plate highlighting a high rate of intraplate intermediate depth events in comparison with interplate and crustal seismicity. Similar observations have been reported by other authors\textsuperscript{47,52}. In the coastal area, the results show a continental crust 30–40 km thick on average with \(V_p\) values of 5.0–6.5 km/s. Similar results were obtained by Contreras-Reyes et al.,\textsuperscript{41} using data from a wide-angle seismic experiment that were interpreted as Palaeozoic intrusive and Jurassic-Triassic intrusive rocks.

In the central depression and beneath the volcanic arc, the seismic results show an upper continental crust layer 10–30 km thick with \(V_p\) values of 5.0–6.6 km/s that overlies a middle continental crust layer (\(V_p \approx 6.6–7.2\) km/s) with a variable thickness between 10 and 30 km (Fig. 2). The middle continental crust overlies a seismic layer \(\sim 20\) km thick (lower crust) with \(V_p\) values higher than typical lowermost crust (7.2 km/s) but lower than typical upper mantle (8.1 km/s) defining a High Velocity Zone (HVZ) compared to typical lower crustal \(V_p\) values. In addition, the HVZ presents \(V_p/V_s\) values of \(\approx 1.75\) consistent with intermediate composition between mafic and ultramafic rocks\textsuperscript{53}. This HVZ was identified in northern Chile by Graeber and Asch\textsuperscript{30}, and interpreted as a thick lower crust or partially hydrated uppermost mantle material. Based on the location of the continental Moho\textsuperscript{45} (Figs. 2 and 3), we interpret the HVZ as the lower portion of the continental crust composed of crystallized melts (former Andean magmas) that underplate the crust causing its thickening continuously as the magmatic arc migrates progressively eastward. Eastward migration of the magmatic arc in northern Chile started at least during the Jurassic causing the displacement of the volcanic arc from the Coastal to Western Cordillera\textsuperscript{29,54,55}. The eastward migration of the magmatic arc in northern Chile (>200 km) has been explained as the consequence of subduction erosion facilitated by the starved trench due to the hyper-arid climate conditions and subduction of rough seafloor\textsuperscript{26,56}.

The location of the continental Moho\textsuperscript{45} (Fig. 2) is coincident with the transition from \(V_p/V_s\) values of 1.75 to 1.8 defining the location of the continental mantle wedge. This spatial correlation fails at the eastward edge of the \(V_p/V_s\) model likely due to the reduced seismic resolution\textsuperscript{46}. The total continental crust thickness in the western magmatic arc is 60–65 km thick, which is consistent with previous seismological studies in the region\textsuperscript{12,25,26,30}. The upper continental mantle velocities are 7.8–8.2 km/s, which is lower than normal mantle rocks (dunite or peridotite; \(V_p \sim 8.36\) km/s at >1 GPa\textsuperscript{27}). According to the laboratory measurements, dry mantle rocks (dunite)
at pressures larger than 1 GPa have $V_p/V_s$ values of about 1.76, while 100% hydrated mantle rocks (serpentinite) have $V_p/V_s$ values of approximately 2.1. Thereby, the estimated $V_p/V_s$ values of 1.75-1.8 for the lithospheric mantle wedge corresponds to mantle serpentinization of 10-15%\(^{53}\), which are lower than the values reported for Costa Rica ($V_p/V_s \sim 1.85$, 15-25% hydration\(^{57}\)) and for Japan ($V_p/V_s \sim 1.87$, \(\sim 30\%\) hydration\(^{58}\)). A low hydration degree in the lithospheric mantle wedge is also consistent with high electrical resistivity values (>10\(^3\) \(\Omega\)m\(^{-1}\)) determined from a 3-D electrical resistivity model generated from magnetotelluric data acquired in northern Chile\(^{59}\). In addition, 3-D body wave seismic tomographic results show a significant contrast in the effects of hydration of the subducted slab on the overriding plate north and south of 21°S\(^{25}\). North of this latitude, high $V_p/V_s$ values (1.78-1.8) are attributed to a larger amount of hydration in the subducted Nazca plate that causes the release of larger volumes of water into the mantle wedge. This mechanism has been suggested to influence the nature of volcanism in the magmatic arc and the coupling of the plate boundary at depths of 20-40 km caused by a greater influx of water due to the subduction of oceanic ridges at 20°-22°S\(^{25}\).

**Electrical resistivity model.** The cross sections extracted from the 3-D electrical resistivity model shows a large zone of reduced \(\rho\) (< 10 \(\Omega\)m) at the back-arc (~400 km landward of the trench axis) along the northernmost profile P01 (Fig. 2). This feature is also present southwards in the back-arc along P02 and P03, but with electrical resistivity values in the range of 1 < \(\rho\) < 10\(^2\) \(\Omega\)m\(^{-1}\).

Along P02-P04, the electrical resistivity model shows zones of variable sizes with high \(\rho\) values (10\(^3\) \(\Omega\)m\(^{-1}\)) bounded by pipe-shaped regions with \(\rho\) values of ~ 10\(^5\) \(\Omega\)m. \(\rho\) values larger than 10\(^2\) \(\Omega\)m fall in the range of igneous and metamorphic rocks\(^{59}\), and probably the regions of reduced electrical resistivity (~ 10\(^2\) \(\Omega\)m) are related to continental rocks with higher hydration and/or metamorphic degree compared to their surroundings. Thus, we interpret these features as the contrast between blocks of relatively low permeability (higher \(\rho\) values) with
more permeable/fractured rocks (lower \( \rho \) values) associated with trans-lithospheric deformation zones. To better illustrate spatially this interpretation, we plot in Fig. 3 the location of the AFZS and DFZS in plan map view with the magnetotelluric model at different depths \( z = 8, 18, \) and 28 km. In the fore-arc, we observe three N-S elongated low resistivity anomalies that spatially correlate with the trace of the AFZS, DFZS, and below the SAB. A NW trend of small high conductivity zones is also observed in Fig. 3 and is coincident with the Tuina-Caspana trans-lithospheric fault proposed by Yañez and Rivera-Herrera (2019)61. Trans-lithospheric deformed zones have been reported by Vauchez and Tommasi (2003)62 and Vauchez et al., (2012)63 in Madagascar, Brazil, and Himalayas among other cases. These authors compile several geophysical models to show a coherent deformation of the entire continental lithosphere crosscutting the continental Moho and deforming the upper mantle.

Relatively high electrical resistivity is also observed beneath the volcanic arc at mid- to lower crustal depth (along P03 and P04; Figs. 2 and 3), while a large region of low \( \rho \) values is observed at the eastern side of the Western Cordillera in the Altiplano morpho-structural unit. These deep and conductive features have been observed in this area in previous studies between 18° and 23.4°S59,64–68 being identified as the Altiplano conductor related to a large volume of inferred partial melt called the Altiplano Puna Magma Body (APMB). The APMB has also been inferred from seismic and gravity studies69–71. High conductivity zones below the trace of AFZS and DFZS were already recognized by magnetotelluric studies at 21°S59,64,72. Similarly, in the Pre-Andean Depression, the SAB region is characterized by a zone of reduced \( \rho \) values (< 1 \( \Omega m \)), which may be caused by high conductivity fluids beneath the salt pan cover at shallow depths. In fact, in-situ conductivity measurements in different water springs inside the Salar de Atacama showed values up to 12.9 S/m at temperatures of \( \sim 25^\circ C \) or equivalent to a \( \rho \) value of 0.077 \( \Omega m \), which is about four times less resistive than the average \( \rho \) value of the seawater (0.3 \( \Omega m \)).

### Discussion

Petrological models predict that metamorphic dehydration processes of the subducting oceanic crust occur at pressures and temperatures higher than 1.2 GPa and 500 °C, respectively1,3. This process leads to the blueschist to eclogite transition that dehydrates most of the water chemically bound in subducting oceanic crust leading to serpentinization of the lithospheric mantle wedge4,30,57,58. However, the electrical resistivity model shows a heterogenous distribution of regions with reduced \( \rho \) values (< 10 \( \Omega m \); Figs. 2-4) usually associated to more
permeable regions. These regions are surrounded by fore-arc blocks of high $\rho$ values ($> 10^4 \Omega m$), which are interpreted as relatively rigid rocks within colder areas of the continental wedge ($< 300 \, ^\circ C$) with reduced presence of aqueous fluids and melts.

Meteoric fluids circulate freely in the upper brittle continental crust and dominate magmatic heat sources. In the lower continental crust (ductile regime), fluids are sourced from devolatilization reactions $^{73,74}$ and are confined to isolated hydraulic domains $^{75-79}$. Such domains would behave as weak inclusions imbedded within adjacent fluid-poor regions $^{29,88}$ and can be connected to an upper crustal drainage network $^{65}$ creating this a trans-lithospheric system of flow. Moreover, the possible absence of a permeability discontinuity or barrier at the brittle/ductile transition zone suggests that fluids stored in high-permeability domains in the lower continental crust can be transmitted to the upper continental crust $^{77}$. In the case of a continental crust that is being thickened and heated (like the Andes case), thermally activated viscous compaction processes allow the expulsion and upward migration of fluids in the lower crust $^{5,78-80}$. In addition, tectonism and streamflow responses to earthquakes demonstrate that dynamic stresses can instantaneously change permeability on a regional scale $^{41}$. Thus, we interpret the low $\rho$ anomalies that traversed the rigid blocks in the fore-arc of relatively high $\rho$ regions as highly fractured and hydrated zones associated to trans-lithospheric deformation zones (AFZS and DFZS). Likely, the AFZS and DFZS favor upward fluid channeling where fluids are sourced by the metamorphic reactions of the subducted slab.

The segmentation of the continental mantle wedge in regions of relatively high and low permeability play an important role in the migration of fluids within the upper plate $^{5,6,7}$ with potential trenchward and arcward paths as has been suggested by numeric models $^{6,82}$. Dehydration reactions from the subducted oceanic crust occurs likely at depths between 30 and <100 km leading to serpentinitization of the overriding continental mantle wedge preferentially in regions of higher permeability. This phenomenon has been widely inferred in several subduction zones by seismological studies $^{25,30,57,58}$. The fluids sourced from the subducting slab (below the LPBs) can further flow updip (trenchwards) along the whole plate boundary $^{82}$, whereas upward fluid migration is more likely controlled by the location of the LPBs as is illustrated in Fig. 5. For instance, Vacher and Rivera-Herrera (2009) $^{49}$ used a flow model in porous media to show that magmatism tends to migrate laterally until it reaches high permeability paths to the surface. They concluded that the upward fluid migration occurs preferentially at the edges of crustal dense blocks in the northern Chilean forearc where the trans-lithospheric fault zone systems are located.

The electrical resistivity model shows that the LPBs are placed both in the continental crust and mantle wedge allowing the connection of the LPB's with fluids flowing along the plate boundary (Figs. 2 and 5). Likely, upward fluid migration occurs at the flanks of the LPBs $^{81,82}$, which coincide with the AFZS and DFZS (Fig. 5). Furthermore, upward fluid circulation along the AFZS and DFZS might favor mineralization processes, the formation of hydrothermal systems and magmatic reservoirs $^{64,71}$ (Figs. 2 and 5).

Beneath the active volcanic arc and eastward of the larger forearc block (LPB in Fig. 5), $\rho$ values decrease again ($< 10^4 \Omega m$). In that zone, at depths >130 km, the thermal model $^{25}$ shows ideal conditions of pressure ($> 2.5 \, GPa$) and temperatures ($> 500 \, ^\circ C$) to produce dehydration reactions from the subducted oceanic mantle causing partial melting and leading to arc volcanism $^{22,25}$ (Fig. 5). Andean magmas are recognized to have a rich felsic, dacitic and rhyolitic compositions $^{25}$, particularly in the segment characterized by the presence of the Altiplano Puna Volcanic Complex (APVC). The APVC is a major volcano tectonic province developed between 21$^\circ$ and 24$^\circ$S in response to a late-Miocene ignimbrite flare-up, with a strong volumetric dominance of ignimbrites and related silicic volcanic rocks over more andesitic compositions $^{25}$. The volcanic complex is developed on one of the thickest parts of the Central Andean crust, which seems to be related to the previous large scale silicic volcanism, initiated at about 10 Ma $^{21}$ as a surface expression of silicic magmatism at depth. This previous large scale volcanism shares a strong physical and petrological resemblance with Late Pleistocene domes as the Chao dacite in Chile $^{84}$ that was found at the western edge of the APVC. However, geophysical and geological evidence from studies carried out in the present days of this segment of the Central Andes suggest the presence of zones of partial melting through the whole crustal column within the APVC, ranging from silicic at shallow levels to mafic compositions at the bottom of the crust $^{19}$.

The results indicate that low-density Andean magmas that buoyantly rises through the heterogenous more permeable regions of the continental plate are subsequently redirected by pressure-temperature and via complex paths as suggested by numeric models $^{61,82}$. For instance, the electrical resistivity model shows a region of relatively high resistivity ($\rho > 10^4 \Omega m$) at 10 to 30 km depth south of Lascar volcano (Figs. 4 and 5), which seems to obstruct the ascent of melts in this area. However, this relative high resistivity zone vanishes at ~30 km depth defining a relatively conductive zone which seems to relate to the western border of the Altiplano conductive anomaly $^{67}$. Melts in this area seem to differentiate and accumulate preferably within the APMB as is observed at the western edges along profiles P1-P4 (Figs. 2 and 3). The interaction of ascending magmas with the surrounding continental crustal rocks also leads to partial melting and the formation of hydrothermal systems at shallow levels. For instance, a small-scale but highly conductive region ($\rho < 1 \Omega m$) can be seen at the trenchward side of the volcanic arc at depths shallower than 10 km, which is coincident with known hydrothermal systems such El Tatio Geysers field, suggesting a possible tectonic control for the crustal emplacement of these features.

The elongated relatively high conductivity zones that correlate with the AFZS and DFZS can be interpreted as extensive damage/deformed zones caused by successive wall rock failure due to the ascent and subsequent depressurization and volatile saturation during the crystallization of the magma chambers $^{22,25}$. Thus, arc magmatism changes the rheology of the overriding plate by thermally weakening deformed zones $^{55,86}$ that were already created by continuous tectonic stresses associated to the subduction system. The combined effect of arc magmatism and tectonic stresses increase the permeability of the deformed zones favoring fluid migration. In particular, the AFZS and DFZS were coincident with active arc magmatism during the Mesozoic $^{46}$ and Paleocene-Oligocene $^{67}$, respectively. Thus, the interplay between tectonic stresses and former arc magmatism
Figure 4. Trench perpendicular geophysical cross section along P03 (23.5°S). (a) 2-D thermal model for northern Chile from Cabrera et al.3. MF: Marine Forearc, CC: Coastal Cordillera, CD: Central Depression, SAB: Salar de Atacama Basin, VA: Volcanic Arc, BA: Back Arc (Puna), OL: Oceanic Lithosphere, AM: Asthenospheric Mantle, and AW: Asthenospheric Wedge (defined by temperatures higher than 1300 °C). (b) Vp, (c) Vp/Vs ratio, and (d) electrical resistivity models. Isotherms are based on the thermal model shown in (a). Orange triangle indicates the location of the main active volcano (Lascar and Miñiques). (e) Geotherms extracted from the 2-D thermal model shown in (a) across x=300 (black curve), 350 (dark green curve), 375 (green light curve), and 400 (purple curve) km long-profile as is shown in (f). The dashed grey curve corresponds to the average mantle rock geotherm beneath a volcanic arc in subduction zones3. The presence of water reduces the solidus temperature (wet-solidus curve) allowing partial melting generation at lower temperatures and lower confining pressures. These physical conditions are reached beneath the volcanic- ≥90 km depth) and back-arcs (≥ 70 km depth). We use the GMT version 5.0 (https://www.generic-mapping-tools.org) and Inskape version 0.97 (https://www.inskape.org/) softwares for generating the plots.
along AFZS and DFZS provide likely the paths for recent redistribution of slab-delivered fluids within the over-riding South American plate (Fig. 5).

**Summary**

The combined analysis of recently published 3-D $V_p$, $V_p/V_s$, and electrical resistivity models reveal the structure of the overriding South American plate in the northern Chilean subduction zone (22°-24°S) from the trench axis up to the back arc. The results lead to the following conclusions:

1. The continental crust is relatively thick (50-65 km) between the Coastal Cordillera and the back arc. The lower part of the continental crust is characterized by a high velocity zone (7.2-7.6 km/s) defining the lower continental crust composed of plutonic rocks.
2. The continental mantle lithospheric wedge is slightly hydrated with $V_p/V_s$ values of 1.75-1.8 compared to other subduction zones such as Costa Rica and Japan ($V_p/V_s \sim 1.85$).
3. The continental crust and mantle wedge are traversed by regions of relatively low electrical resistivity ($\sim 10^2 \Omega \text{m}$) compared to their surroundings ($\sim 10^3 \Omega \text{m}$). In addition, the shallower parts of the relatively low electrical resistivity regions spatially correlate with the Atacama and Domeyko Fault Zone systems.
4. We interpret the relatively low electrical resistivity regions as zones of higher permeability/fracturing and fluid content associated with the trans-lithospheric deformation zones (Atacama and Domeyko Fault Zone systems). Melt and fluids derived from dehydration reactions from the subducting slab follow complex trench- and arc-ward paths as is suggested by the heterogeneity of the 3-D electrical resistivity model.
Methods
Seismological data and modeling. Comte et al.25 determined 3D body wave seismic tomography in northern Chile, incorporating surface wave observations to adjust the model before the joint inversion. The data used compromises 342 short-period seismic stations deployed in northern Chile over several decades and 18 broadband stations operated by IPOC, CSN, and ONEMI over three years (1/1/2012–12/31/2014). The data corresponded to a combination of arrival times from earthquake-generated body waves and transit times from ambient noise generated surface waves recorded by seismic stations deployed in northern Chile for different periods over the past three decades. The initial body wave data set derived from these deployments consisted of P and S arrival times from 33,351 events recorded over a period of 25 years by a variety of networks comprising 360 stations. From this data set, earthquakes that were recorded by at least 10 stations and with predicted arrival times within an initial outlier residual threshold of the larger of 2 seconds and 10% of the total travel time, were selected. Application of these criteria resulted in a reference data set of 11,874 events with 110,640 P and 106,680 S wave arrival times. The simultaneous fitting of body wave arrival times and surface wave transit times was done to determine a 3D body wave seismic tomography. Surface waves were included to reduce potential trade-offs in crustal and mantle structures caused by the lack of local shallow earthquake activity. Surface waves also provided additional constraints on shear wave speeds that compensate for the lower number of, and higher uncertainties in, shear wave arrival times.

The joint inversion methodology was based on an approach described in Roecker et al.88,89. The subsurface was then parameterized by specifying P and S velocities on a 3D grid of nodes spaced at 5 km intervals in depth and latitude about the same distance in longitude. Intragrid velocities were determined by trilinear interpolation. Body wave travel times within the medium were calculated using a 3D Eikonal equation solver in a spherical coordinate system. Hypocenter coordinates were included as variables in the inversion, but they were also relocated in the updated models before any iteration. The models generally needed 10 iterations with only surface wave times followed by an additional 10 iterations with combined surface and body wave times. In this way, Comte et al.25 determined that the best way to incorporate surface wave observations was to allow them to adjust the model prior to the joint inversion. For the starting model of the surface wave only inversion, they began with a body wave only inversion that started with an adaptation of the 1D model of Husen et al.90 for the Antofagasta region. The resulting 3D body wave model for Vp and Vs/Vs obtained after 13 iterations, was averaged laterally to obtain a 1D estimate of Vs, ensuring some compatibility with the body waves and provides a means for determining appropriate values for regularization and thresholds for data misfit. Because surface wave inversions tend to retain biases introduced by interfaces like the Moho, they smoothed the transition from crustal to mantle velocities over a range of depths (40–70 km) suggested by previous estimates of crustal thickness in this area.26,27. This 1D Vs model was then used as a starting model for the surface wave inversion. After 10 iterations of the surface wave inversion, the velocities in the resulting 3D Vs model were then multiplied by a constant Vp/Vs ratio to construct a starting 3D Vp and Vs model for the joint inversion. Based on both the results from the body wave inversion and a linear fit to Tp vs Ts for the entire body wave data set, a Vp/Vs = 1.76 was obtained as the preferred value. Several trial inversions were also performed to evaluate the effects of a variety of assumptions and choices of parameters on the final model. As a result of the trials, they concluded that the first order features in the preferred model are robust. Specifically, the increase in Vp/Vs from the subducted slab into the supra-slab mantle, as well as the size and location of the high Vp/Vs regions, appeared well constrained. These features are reasonably independent of the starting model, but the actual values of Vp/Vs tend to stay close to the starting value. While large gradients in Vp, Vs, and Vp/Vs were well constrained, localized regions with small changes (on the order of 1%) are not significant.

Electrical resistivity model. The magnetotelluric (MT) method is a passive surface geophysical technique that uses the time-varying natural electromagnetic (EM) fields to study the electrical resistivity distribution at depth.90,92. The relationships between horizontal electric field (Eh) and magnetic (Hh) fields on the surface defined the transfer functions Z (impedance tensor) and T (tipper) that depend on the distribution of electrical resistivity in the subsurface.9. To obtain a model of the electrical resistivity structure of the lithosphere, a dataset consisting of 58 MT stations at an array of sites distributed between 22° and 24.5°S was used. All measurements were carried out in a geographic coordinate system, with the x-axis pointing to the geomagnetic north and the y-axis pointing to the geomagnetic east. For the 3-D inversion, 20 periods equally distributed between 10 and 10,000 s were used. The 3-D electrical resistivity model has been obtained from the inversion of the four components of Z and the two T components using the ModEM code,93, an EM inverse modeling program based on a standard minimum structure, non-linear conjugate gradients algorithm (NLCG).
