Abstract

Deterministic Policy Gradient (DPG) removes a level of randomness from standard randomized-action Policy Gradient (PG), and demonstrates substantial empirical success for tackling complex dynamic problems involving Markov decision processes. At the same time, though, DPG loses its ability to learn in a model-free (i.e., actor-only) fashion, frequently necessitating the use of critics in order to obtain consistent estimates of the associated policy-reward gradient. In this work, we introduce Zeroth-order Deterministic Policy Gradient (ZDPG), which approximates policy-reward gradients via two-point stochastic evaluations of the $Q$-function, constructed by properly designed low-dimensional action-space perturbations. Exploiting the idea of random horizon rollouts for obtaining unbiased estimates of the $Q$-function, ZDPG lifts the dependence on critics and restores true model-free policy learning, while enjoying built-in and provable algorithmic stability. Additionally, we present new finite sample complexity bounds for ZDPG, which improve upon existing results by up to two orders of magnitude. Our findings are supported by several numerical experiments, which showcase the effectiveness of ZDPG in a practical setting, and its advantages over both PG and Baseline PG.

1 Introduction

Reinforcement Learning (RL) has proven itself a well-known and effective approach for tackling dynamic optimization problems, and is ubiquitous in many application areas [11], such as robotic manipulation [16], supply chain management [10], games [26, 29], and wireless communications [32, 5], to name a few. A general approach for solving RL problems is policy search, which relies on directly learning a policy to maximize rewards through interaction with an unknown environment. Hypothesizing that actions are chosen according to a parameterized distribution (a.k.a. a randomized policy), Policy Gradient (PG) is a type of policy search algorithm that repeatedly updates its policy through a specially-derived stochastic gradient [28], enabling solutions in complex problems with continuous state-action spaces. Backing its empirical success are a range of theoretical guarantees including guaranteed policy improvement with smoothness assumptions [24], sample complexity bounds [33], and variance reduction [22].

Deterministic Policy Gradient (DPG) considers RL problems by naturally assuming that the policy is a deterministic mapping from states to actions [27]. This formulation removes policy randomization, otherwise integral to classical PG, and permits the complete characterization of the gradient of the
We also present detailed analysis characterizing the convergence rate of our proposed ZDPG algorithm with standard PG and DPG. ZDPG enjoys the following additional operational advantages:

- As with DPG, ZDPG eliminates the need for randomized policies. Although we are not the first to achieve this goal [27], we would still like to perpetuate the narrative that randomized policies, although most common, are not really necessary in PG-based RL.
- At the same time, while ZDPG exploits gradient information of the adopted (and known) policy parameterization, it restores true model-free policy learning (as in standard PG); this is naturally lost in DPG, where the use of an auxiliary critic is typically invoked [27].
- ZDPG enjoys built-in and provable quasi-gradient variance stability (albeit at the expense of an additional system rollout), which is very similar in principle to (heuristic) baseline PG techniques [11].

In this work, we introduce Zeroth-order Deterministic Policy Gradient (ZDPG), which advocates the use of (zeroth-order) noisy estimates of the $Q$-function for approximating the corresponding (deterministic) policy-reward gradient, in the standard infinite horizon MDP formulation. In particular, by exploiting the recently introduced idea of random horizon rollouts for obtaining unbiased stochastic estimates of the $Q$-function [23, 33], we show that it is possible to efficiently construct consistent two-point approximations (single or in batches) of the associated policy-reward gradient [4, 20]; this is achieved by evaluating pairs of the $Q$-function at low-dimensional random action-space perturbations, involving initial actions only. Such a construction is rather important from a computational perspective, for two main reasons. First, for most popular choices of policy parameterizations (e.g., Deep Neural Networks (DNNs)), the dimension of the corresponding parameter space is typically much larger than the dimension of the action space, where our random perturbations are introduced [30]. This is a key feature, because it is well-known that the dimension of the perturbation space has drastic negative effects on the performance of zeroth-order methods [4, 20]. Second, the fact that we (randomly) perturb only the initial action of the underlying dynamic program makes our ZDPG approach readily implementable, and easily applicable to the infinite horizon setting. As compared with standard PG and DPG, ZDPG enjoys the following additional operational advantages:

| Smoothness Parameter ($\mu$) | Number of Rollouts ($N$) | Stepsize ($\alpha$) | Grad-Lipschitz $Q$-function | Hessian-Lipschitz $Q$-function |
|-------------------------------|------------------------|--------------------|-----------------------------|-------------------------------|
| $T^{-1/4}$                    | 1                      | $T^{-1/2}$         | $O(\epsilon^{-4})$          | $O(\epsilon^{-2})$            |
| $T^{-3/4}$                    | $T^{-1/2}$             |                   | $O(\epsilon^{-3})$          | $O(\epsilon^{-2})$            |
|                               | $T^{-2/3}$             |                   |                             |                               |

We also present detailed analysis characterizing the convergence rate of our proposed ZDPG algorithm under common problem regularity conditions. From a technical standpoint, our analysis is different from that of conventional zeroth-order methods for nonconvex optimization – which follows the general structure of defining a smoothed surrogate objective (reward), analyzing the convergence of the resulting smoothed problem, and then relating those results back to the original problem (see, e.g., [15] [13]). More specifically, our convergence analysis is based on the explicit construction of a smoothed policy-reward gradient surrogate (not necessarily corresponding to the gradient of some smoothed objective surrogate), which admits a zeroth-order representation matching exactly our rollout-pair-based two-point policy-reward gradient approximations. A key feature of the proposed gradient surrogate is that it constitutes a uniform approximation to the true (deterministic) policy-reward gradient of Silver et al. [27]. This fact is then exploited to analyze the resulting stochastic quasi-gradient algorithm (ZDPG) as a method for solving the original DPG problem, directly.

Our rate results are summarized in Table 1. Specifically, we show that under the assumption of a Lipschitz and smooth $Q$-function, ZDPG with a single rollout pair achieves a rate of order $O(\epsilon^{-4})$
We consider a Reinforcement Learning (RL) problem where an agent moves through a state space \( S \) where \( \rho \) (given accuracy \( \epsilon > 0 \)), whereas if the \( Q \)-function has also Lipschitz Hessian, ZDPG achieves a rate of order \( O(\epsilon^{-3}) \). If, further, multiple rollout pairs are available (mini-batch equivalent), then the aforementioned rates both improve to an order of \( O(\epsilon^{-2}) \), in which case the number of rollout pairs are precisely \( T \) and \( \sqrt{T} \), respectively, where \( T \) is the total number of ZDPG iterations. To the best of our knowledge, our results are the first of their kind pertinent to the standard infinite horizon setting, also outperforming previous results reported for the finite horizon setting [50] by up to two orders of magnitude (depending, of course, on problem conditioning).

The performance of ZDPG is empirically evaluated on a point agent navigation problem at the presence of environment obstacles, where there is no knowledge of the system dynamics. Our numerical results demonstrate that ZDPG substantially outperforms both standard PG and PG with a baseline, under both noiseless and noisy system dynamics, and in terms of both mean performance and its variance. In particular, our simulations elucidate the fact that ZDPG enjoys clear operational advantages over PG with a baseline, which may be considered as the analogous two-point update for the stochastic policy setting.

2 Deterministic Policy Gradient

We consider a Reinforcement Learning (RL) problem where an agent moves through a state space \( S \) and takes actions from an action set \( A \), both assumed to be continuous and compact, i.e., \( S \subset \mathbb{R}^d \) and \( A \subset \mathbb{R}^p \). The agent’s task is to accumulate as much reward as possible in the long term, where the reward is revealed to the agent by the environment at each step. This generic problem may be circumvented this complexity, the policy is parameterized by some \( \theta \in \Theta \subset \mathbb{R}^d \) so that the search is over a Euclidean space of finite dimension. The problem of interest consequently becomes

\[
Q^\pi(s, a) := \mathbb{E} [R(s, a) + \gamma \mathbb{E} [V(s')]] = \mathbb{E} \left[ R(s_0, a_0) + \sum_{t=1}^{\infty} \gamma^t R(s_t, \pi(s_t)) \bigg| s_0 = s, a_0 = a \right].
\]

The \( Q \)-function determines the quality of taking an action \( a \) at state \( s \) and then following policy \( \pi \) for the remainder of time. By selecting the first action according to the policy, the \( Q \)-function is equivalent to the value function, and hence the problem (3) is equivalently written as

\[
\max_\pi \mathbb{E}_{s \sim \rho^0} [Q(s, \pi(s))].
\]

Solving (3) requires searching over a function space, which is generally an intractable problem. To circumvent this complexity, the policy is parameterized by some \( \theta \in \Theta \subset \mathbb{R}^d \) so that the search is over a Euclidean space of finite dimension. The problem of interest consequently becomes

\[
\max_\theta \mathbb{E}_{s \sim \rho^0} [Q^{\pi_\theta}(s, s')] =: J(\theta).
\]

In their seminal work [27], Silver et al. proved that the gradient of (4) can be expressed by

\[
\nabla J(\theta) = \mathbb{E}_{s \sim \rho^\pi} \left[ \nabla_\theta \pi_\theta(s) \nabla_a Q^{\pi_\theta}(s, a) |_{a = \pi_\theta(s)} \right],
\]

where \( \rho^\pi \) is the discounted state distribution \( \rho^\pi(s') = \int_S \sum_{t=1}^{\infty} p_0(s)p(s \rightarrow s', t, \theta)ds, \) and \( p(s \rightarrow s', t, \theta) \) denotes the density at state \( s' \) after starting form state \( s \) and transitioning with \( t \) time steps given policy parameterized by \( \theta \). Next, we formally define some standard assumptions on the policy gradient, reward function, and \( Q \)-function, as follows.
Assumption 1 (Bounded Policy Gradient) The policy gradient $\nabla_\theta \pi_\theta(s)$ is uniformly bounded on $\Theta \times S$, i.e., there is $B_\Theta < \infty$, such that $\sup_{(\theta,s) \in \Theta \times S} \| \nabla_\theta \pi_\theta(s) \| \leq B_\Theta$.

Assumption 2 (Bounded Rewards) The reward $R$ is uniformly bounded on $S \times A$, i.e., there is $U_R < \infty$, such that $\sup_{(s,a) \in S \times A} |R(s,a)| \leq U_R$.

By Assumption 2, it also follows that the $Q$-function is also uniformly bounded as

$$|Q^\pi(s,a)| \leq \sum_{t=0}^{\infty} \gamma^t \cdot U_R = \frac{1}{1-\gamma} U_R =: Q.$$

Both Assumptions 1 and 2 are standard for deriving performance guarantees in the policy search literature [33, 18, 2], and are easily satisfied by common choices of the deterministic policy and reward functions. Additionally, we require sufficient smoothness of the $Q$-function, as follows.

Assumption 3 (Lipschitzness of the $Q$-function) The $Q$-function is action-Lipschitz uniformly on $\Theta \times S$. That is, there is a number $L < \infty$, such that, for every $a_1, a_2 \in A$,$$
\sup_{(\theta,s) \in \Theta \times S} |Q^\pi(s,a_1) - Q^\pi(s,a_2)| \leq L \| a_1 - a_2 \|.$$ 

Assumption 4 (Smoothness of the $Q$-function) The $Q$-function is action-smooth uniformly on $\Theta \times S$. That is, there is a number $G < \infty$, such that, for every $a_1, a_2 \in A$,$$
\sup_{(\theta,s) \in \Theta \times S} \| \nabla_a Q^\pi(s,a_1) - \nabla_a Q^\pi(s,a_2) \| \leq G \| a_1 - a_2 \|.$$ 

Intuitively, Assumptions 3 and 4 means that similar actions from the same state should have similar values. This principle has informed Actor-Critic algorithms in practice as they are known to avoid overfitting to narrow peaks in the value estimate [7]. Furthermore, existing convergence analysis for zeroth-order action space exploration with finite horizon use these assumptions as well [30]. Lastly, in some of our results we assume that the problem is well-conditioned with Lipschitz Hessians.

Assumption 5 (Smoothness of $\nabla Q$) The gradient field $\nabla Q$ is action-smooth uniformly on $S$. That is, there is a number $H < \infty$, such that, for every $a_1, a_2 \in A$,$$
\sup_{s \in S} \| \nabla^2_a Q^\pi(s,a_1) - \nabla^2_a Q^\pi(s,a_2) \| \leq H \| a_1 - a_2 \|.$$ 

Assumption 5, though not entirely standard, holds for a variety of problems with well behaved reward functions and policy representations, such as the Linear Quadratic Regulator (LQR) [6] and its many (and potentially nonlinear) variations. A reward function may be designed to achieve such an assumption, as well [21]. The trade-off between our various smoothness assumptions and the convergence rates achieved in this work is demonstrated in Table 1.

In order to compute a stochastic approximation of $\nabla Q$, we need to both sample from the discounted state distribution $\rho^\pi(s)$ and evaluate the gradient expression. Because the policy is deterministic, $\nabla_\theta \pi_\theta(s)$ is the Jacobian of the policy $\pi_\theta$ evaluated at $s$ which can be explicitly calculated. Instead of using a critic network to estimate the $\nabla_a Q^\pi(s,a)$ [27], which requires many state-action-reward samples before converging to something meaningful, we propose the use of two point zeroth-order action space perturbed $Q$-function estimates. In the following section, we review how to use zeroth-order information to evaluate stochastic gradient estimates.

2.1 Zeroth-order Gradient Estimates

First, we introduce a smoothed approximation to the $Q$-function by exploiting low-dimensional perturbations with respect to the action $a$. Let $\mu > 0$ be the smoothing parameter, and let $u \sim \mathcal{N}(0,\mathcal{I}_P)$. Then, the $\mu$-smoothed $Q$-function is defined as

$$Q^\pi_\mu(s,a) := \mathbb{E}_u [Q^\pi(s,a + \mu u)].$$

By introducing smoothing, we are able to sample an unbiased stochastic estimate of $\nabla_a Q^\pi_\mu(s,a)$ via a two-point evaluation of the original $Q$-function. Namely, we recall the following key property (in terms of the $Q$-function), true in general for every globally Lipschitz function as originally presented in [15], then extended to a wider class of functions in [15].
Algorithm 1 Zeroth-order Deterministic Policy Gradient

Require: \( \theta_0, \gamma, \mu, \alpha, N \)

for \( t = 0, 1, \ldots \) do
    Sample \( T_Q \sim \text{Geom}(1 - \gamma) \)
    Sample \( s_t \sim \rho^{\pi_t} \), Algorithm 3 with \( (T, \theta) = (T_Q, \theta_t) \)
    Sample \( u \sim \mathcal{N}(0, I_p) \)
    Initialize Estimates \( \hat{Q}_t^+ \leftarrow 0, \hat{Q}_t^- \leftarrow 0 \)
    for \( n = 0, 1, \ldots, N - 1 \) do
        \( Q_{t,n}^+ \leftarrow \text{Algorithm 2} \) with \( (T, s_0, a_0, \theta) = (T_Q, s_t, \pi_{\theta_t}(s_t) + \mu u, \theta_t) \)
        \( Q_{t,n}^- \leftarrow \text{Algorithm 2} \) with \( (T, s_0, a_0, \theta) = (T_Q, s_t, \pi_{\theta_t}(s_t), \theta_t) \)
        \( Q_t^+ \leftarrow \hat{Q}_t^+ + \frac{1}{N} Q_{t,n}^+ \)
        \( Q_t^- \leftarrow \hat{Q}_t^- + \frac{1}{N} Q_{t,n}^- \)
    end for
    Evaluate \( \Psi_t = \nabla_{\theta} \pi_{\theta_t}(s_t) \)
    \( g_t \leftarrow \Psi_t \left( \frac{\hat{Q}_t^+ - \hat{Q}_t^-}{\mu} \right) u \)
    \( \theta_{t+1} \leftarrow \theta_t + \alpha g_t \)
end for

Lemma 1 [15] Lemma 2] For every \( \mu > 0 \), the \( \mu \)-smoothed Q-function surrogate \( Q^{\pi\theta}_\mu \) is differentiable, and its gradient admits the representations

\[
\nabla_a Q^{\pi\theta}_\mu(s, a) \equiv \mathbb{E}_{u \sim \mathcal{N}(0, I_p)} \left[ \frac{Q^{\pi\theta}(s, a + \mu u) - Q^{\pi\theta}(s, a)}{\mu} u \right]
\]

\[
\equiv \mathbb{E}_{u \sim \mathcal{N}(0, I_p)} \left[ \frac{Q^{\pi\theta}(s, a + \mu u) - Q^{\pi\theta}(s, a - \mu u)}{2\mu} u \right].
\]

(6)

Driven by Lemma 1 we propose the following estimate of the objective gradient defined in (5) where, instead of the true gradient \( \nabla_a Q^{\pi\theta}(s, a) \) we use the smoothed gradient \( \nabla_a Q^{\pi\theta}_\mu(s, a) \) to obtain the quasi-gradient

\[
\nabla J(\theta) = \mathbb{E}_{s \sim \rho^{\pi\theta}} \left[ \nabla_{\theta} \pi_{\theta}(s) \nabla_a Q^{\pi\theta}_\mu(s, a)|_{a = \pi_{\theta}(s)} \right].
\]

(7)

Lemma 1 provides a procedure to obtain an unbiased estimate of \( \nabla_a Q^{\pi\theta}_\mu(s, a) \), which is to sample \( u \sim \mathcal{N}(0, I_p) \) and then evaluate the Q-function with initial actions \( a \) and \( a + \mu u \). By selecting the smoothing parameter \( \mu \) sufficiently small, the gradient estimate becomes close to the deterministic policy gradient (see Section 3, Theorem 1). Obtaining two samples of the Q-function at a specific state may not be practical on a real system, but can be made feasible through the use of simulators which allow resetting and reproduction of the same stochastic environment [23]. The resulting algorithm using the two point zeroth-order gradient estimate is presented in pseudocode in Algorithm 1 where \( \alpha \) is the policy parameter stepsize. We employ Monte-Carlo variance reduction by running the system \( N \geq 1 \) times (\( N = 1 \) implies no reduction).

Algorithm 1 functions with the assumption that both an unbiased estimate of the Q-function evaluated at any state-action pair as well as sampling from the discounted state distribution \( \rho^{\pi\theta} \) is feasible. Here, we describe both procedures which involve sampling a horizon length from a geometric distribution. In [23] Proposition 2), it was shown that the procedure described by Algorithm 2 results in unbiased estimates of the Q-function defined by (5). As the next result asserts, the aforementioned estimates are of finite variance, as well. Due to lack of space, we defer all subsequent proofs of our theoretical results to the supplementary material.

Lemma 2 Let Assumption 2 be in effect. Then, the estimate \( \hat{Q} \) produced by Algorithm 3 is of bounded variance, independent of the inputs of Algorithm 3.

For later reference, let \( w_{t,n}^\pm := \hat{Q}_{t,n}^\pm - Q^{\pi\theta_t}(\pm), \) where \( \pm \) refers to the respective initial state-action pair. Also introduced in [23], Algorithm 3 describes a similar procedure to obtain samples \( s_t \sim \rho^{\pi_t} \).
Alternatively, under Assumption 5, it holds that

\[ J \]

We are now ready to state our main theorem, which establishes the convergence rate of Algorithm 1

\[ \hat{J} \]

Let Assumptions 1-3 be in effect. Further let the objective function gradient \( J \) be \( L \)-smooth and \( G_j \)-Lipschitz continuous. Then, under Assumption 4, it is true that

\[ \frac{1}{T} \sum_{t=1}^{T} E \left[ \| \nabla \theta_j(\theta_t) \|^2 \right] \leq \begin{cases} O \left( \frac{p^2T^{-1/4}}{} \right), & \text{if } (N, \alpha, \mu) = (1, T^{-3/4}, T^{-1/4}) \\ O \left( \frac{p^2T^{-1/2}}{} \right), & \text{if } (N, \alpha, \mu) = (T, T^{-1/2}, T^{-1/2}) \end{cases} \]

Alternatively, under Assumption 5, it holds that

\[ \frac{1}{T} \sum_{t=1}^{T} E \left[ \| \nabla \theta_j(\theta_t) \|^2 \right] \leq \begin{cases} O \left( \frac{p^2T^{-1/3}}{} \right), & \text{if } (N, \alpha, \mu) = (1, T^{-2/3}, T^{-1/6}) \\ O \left( \frac{p^2T^{-1/2}}{} \right), & \text{if } (N, \alpha, \mu) = (T^{1/2}, T^{-1/2}, T^{-1/4}) \end{cases} \]
Theorem 2 requires that the objective function $J(\theta)$ is smooth and Lipschitz. This is is easily satisfied under all Assumptions whenever that the adopted policy parameterization is sufficiently well-behaved. A smooth policy serves this purpose, for instance. Further, for simplicity, we have presented Theorem 2 for the unconstrained setting, where $\Theta = \mathbb{R}^d$. In practice, though, we may need to constrain the parameters. In this case, Theorem 2 continues to hold (almost), but with the squared gradient norm being replaced by the merit function $\|\Pi_{\Theta}\{\theta_t + \alpha \nabla J(\theta_t)\} - \theta_t\|^2/\alpha^2$; see, e.g., [9].

4 Numerical Results

In this section, we empirically evaluate ZDPG and compare its performance to vanilla Policy Gradient (PG) [28] and Policy Gradient with Baseline (PG-B) [11] with varying levels of system noise and MC variance reduction. First, we formally describe the Markov Decision Process we choose to solve, then we present our results and discuss the key takeaways.

4.1 Problem Setting: Navigating Around an Obstacle with Unknown Agent Dynamics

For our empirical evaluation of ZDPG, we consider a two-dimensional continuous state-action navigation problem, where a point agent aims to avoid a spherical (for simplicity) obstacle and converge fast to some fixed target while satisfying its motion control dynamics. This goal is achieved by appropriately shaping the associated reward function. Let $s^* \in \mathbb{R}^2$ represent the target the point agent wishes to reach. Let $s^c \in \mathbb{R}^2$ and $r \in \mathbb{R}_+$ denote the center and radius of the spherical obstacle the agent wishes to avoid. Then, we define the reward $R : \mathbb{R}^2 \to \mathbb{R}$ as a combination of two artificial potential functions: An attractive potential $\phi^{\text{att}} : \mathbb{R}^2 \to \mathbb{R}_+$ with a maximum at the target, and a repulsive artificial potential $\phi^{\text{rep}} : \mathbb{R}^2 \to \mathbb{R}_+$ with a minimum at the center of the object. Specifically, we set the attractive potential to be the negative Euclidean distance to the goal location $s^*$ squared, that is, $\phi^{\text{att}}(s) := -\|s - s^*\|_2^2$, where $s$ is the location (state) of the agent. Similar to [14], we define the repulsive potential as $\phi^{\text{rep}}(s) := 1 - 1/\beta(s)$, where

$$\beta(s) := \left(1 - \frac{1 + r^4}{r^4}\right) \cdot \left(\frac{\|s - s^c\|^2 - r^2}{1 + (\|s - s^c\|^2 - r^2)^2}\right)^{\frac{1}{2}} \cdot (1 - \text{sign}(\|s - s^c\| - r))$$

Completely characterized by the state of the agent, the reward is equal to the sum of these attractive and repulsive potentials, that is, $R(s) = \phi^{\text{att}}(s) + \phi^{\text{rep}}(s)$. Also, the motion dynamics of the point agent are described by the controlled random walk

$$s_{t+1} = As_t + \eta \frac{\pi_\theta(s_t)}{\|\pi_\theta(s_t)\|} + n_t,$$

where $A \in \mathbb{R}^{2 \times 2}$ is the motion state transition matrix of the agent, $\{n_t\}$ is a random process modeling state process noise, and $\eta > 0$ (together with policy normalization) imposes implicit resource constraints on the agent motion. Here, we assume that, except from the agent control vector (second term on the right-hand side of (5)), the dynamics of the agent are unknown, an assumption which conforms with the standard policy gradient setting. Lastly, we consider a linear, deterministic policy to determine optimal directions that the point agent will follow given its location to its prescribed destination. In particular, we adopt a Radial-Basis-Function (RBF) expansion as our (universal) policy parameterization, i.e.,

$$\pi_\theta(s) = \sum_{i=1}^d \theta_i \kappa(s, \bar{s}_i),$$

where $\kappa(s, s') = \exp(-\|s - s'\|_2^2/2\sigma^2)$ defines the RBF kernel, $\theta_i \in \mathbb{R}^2$, $i = 1, \ldots, d$ are the parameter vectors to be learned, $\sigma^2$ determines the variance of the kernel, and $\bar{s}_i, i = 1, \ldots, d$ are the associated RBF centers.

For all simulations, we select the target of the agent to be located at $s^* = (-5, -5)$, and the obstacle to be centered at $s^c = (0, 0)$ with a radius of $r = 2.5$. We define the potential with a slightly larger radius ($r = 3$) to ensure that the agent does not collide with the boundary of the obstacle. We select the centers of the RBF kernels to be spaced 0.25 units from each other populating the $[-10, 10] \times [-10, 10]$ grid. The initial state distribution is uniform on $[-10, 10] \times [-10, 10]$. 

7
4.2 Results

The learning curves shown in Figure 1 show the performance of ZDPG compared to PG and PG-B with discount factor $\gamma = 0.8$ in the case with and without system noise ($n_t = 0$ and $n_t \sim \mathcal{N}(0, \omega \cdot I_2)$ respectively). Also, we set $A = I_2$. For PG and PG-B, we let $\tilde{\pi}$ denote the stochastic policy where the action is selected by $a_t \sim \tilde{\pi}_\theta(s_t)$. In particular, we let $\tilde{\pi}$ be a Gaussian policy with mean equal to $\pi_\theta(s)$ [c.f. (9)] and a standard choice of covariance matrix $\Sigma = 0.5 \cdot I_2$. After each policy update, we evaluate the system by generating a rollout of fixed length $T = 20$ from a fixed starting point $s^0 = (5, 5)$. As done commonly in practice (as a heuristic), we evaluate the stochastic policies by setting the covariance matrix equal to zero thereby making the evaluation policy deterministic.

Depending on the level of the system noise, ZDPG consistently outperforms PG-B (and also PG), both in mean performance and the associated variance. Naturally, the improvement of ZDPG over PG-B is smaller when the agent dynamics are noisy. Note that the update of PG-B is analogous to ZDPG in that it scales the update direction $\nabla_\theta \log \tilde{\pi}_\theta(s)$ by a two-point difference ($Q(s, a) - V(s)$).

We observe that, without any system noise, the perturbation of the initial state with a deterministic policy indeed provides more meaningful information for policy improvement than in the setting of a stochastic policy (also see Figure 2). However, when the system noise increases, the initial perturbations become less informative. This suggests the use of symmetric perturbations [see (6)] in noisy settings with a potentially larger smoothness parameter. One should also note that PG-B performs better in the noisy setting (1 (a)) than the noiseless setting (1 (a)). This is because variance reduction is used in the latter setting, which improves its performance. We emphasize though that we
evaluate stochastic policies using only their means. Our empirical results corroborate the claim that randomness in the policy is not necessary to solve MDPs within the PG-based RL framework.

5 Conclusions and Future Work

In this work, we introduced a two point zeroth order estimate of the deterministic policy gradient for the infinite horizon Markov Decision Problem. Using random horizon to evaluate the zeroth order estimates of the state action function, we showed that perturbations in the action space replace the need for randomized policies in the classical policy gradient setting. We presented finite sample complexity results which improved upon existing by up to two orders of magnitude. Finally, we corroborated our results with a numerical evaluation on a navigation problem which showcased the advantages of our method over both standard PG and PG with baseline. For future work, MC variance reduction could be replaced with more sample efficient variance reduction techniques, such as gradient averaging or using a critic network to evaluate zeroth order state action function.

Supplementary Material

A Proof of Lemma\textsuperscript{[2]}

Since the estimate \( \bar{Q} \) is unbiased, it suffices to show that \( \mathbb{E}[|\bar{Q}|^2] \) is bounded. Indeed, we have

\[
\mathbb{E}[|\bar{Q}|^2] = \mathbb{E} \left[ \left( \sum_{t=0}^{T-1} R(s_t, a_t = \pi_{\theta}(s_t)) \right)^2 \right] \leq \mathbb{E} \left[ \left( \sum_{t=0}^{T-1} |R(s_t, a_t = \pi_{\theta}(s_t))| \right)^2 \right] \leq \mathbb{E} \left[ T^2 U^2 \right] = U^2 \frac{1 + \gamma}{(1 - \gamma)^2},
\]

where the last equality follows from the fact that \( T \) is a geometric random variable with probability of success \( 1 - \gamma \). Enough said.

B Proof of Theorem\textsuperscript{[1]}

Let Assumptions\textsuperscript{[1,3]} and also Assumption\textsuperscript{[4]} be in effect. Also, recall the definitions of the gradients, namely

\[
\nabla J(\theta) = \mathbb{E}_{s \sim \rho^\theta} \left[ \nabla_{\theta} \pi_{\theta}(s) \nabla_{a} Q_{\pi_{\theta}}(s, a) \right]_{a = \pi_{\theta}(s)},
\]

and

\[
\hat{\nabla} J(\theta) = \mathbb{E}_{s \sim \rho^\theta} \left[ \nabla_{\theta} \pi_{\theta}(s) \nabla_{a} Q_{\pi_{\theta}}(s, a) \right]_{a = \pi_{\theta}(s)}.
\]

By definition, and then by Jensen, we have

\[
\| \nabla J(\theta) - \hat{\nabla} J(\theta) \| = \mathbb{E}_{s \sim \rho^\theta} \left[ \| \nabla_{\theta} \pi_{\theta}(s) \nabla_{a} Q_{\pi_{\theta}}(s, a) \|_{a = \pi_{\theta}(s)} - \| \nabla_{\theta} \pi_{\theta}(s) \nabla_{a} Q_{\pi_{\theta}}(s, a) \|_{a = \pi_{\theta}(s)} \right] \leq \mathbb{E}_{s \sim \rho^\theta} \left[ \| \nabla_{\theta} \pi_{\theta}(s) \| \cdot \| \nabla_{a} Q_{\pi_{\theta}}(s, a) \|_{a = \pi_{\theta}(s)} - \| \nabla_{a} Q_{\pi_{\theta}}(s, a) \|_{a = \pi_{\theta}(s)} \right].
\]

Grouping terms, then applying Cauchy-Schwarz, we obtain

\[
\| \nabla J(\theta) - \hat{\nabla} J(\theta) \| \leq \mathbb{E}_{s \sim \rho^\theta} \left[ \left\| \nabla_{\theta} \pi_{\theta}(s) \left( Q_{\pi_{\theta}}(s, a) - \nabla_{a} Q_{\pi_{\theta}}(s, a) \right) \right\|_{a = \pi_{\theta}(s)} \right] \leq B_{\theta} \mathbb{E}_{s \sim \rho^\theta} \left[ \left\| \nabla_{\theta} \pi_{\theta}(s) \left( Q_{\pi_{\theta}}(s, a) - \nabla_{a} Q_{\pi_{\theta}}(s, a) \right) \right\|_{a = \pi_{\theta}(s)} \right] \leq B_{\theta} \mathbb{E}_{s \sim \rho^\theta} \left[ \left\| \nabla_{\theta} \pi_{\theta}(s) \right\| \cdot \left\| G_{1} \right\| \right] \leq B_{\theta} \mu \sqrt{\beta} G_{1},
\]

where the final inequality comes from \textsuperscript{[20] Lemma 1].

If, alternatively, Assumption\textsuperscript{[5]} instead of Assumption\textsuperscript{[4]} holds, then by \textsuperscript{[20] Lemma 3], we obtain

\[
\| \nabla J(\theta) - \hat{\nabla} J(\theta) \| \leq B_{\theta} \mathbb{E}_{s \sim \rho^\theta} \left[ \left\| \nabla_{\theta} \pi_{\theta}(s) \left( Q_{\pi_{\theta}}(s, a) - \nabla_{a} Q_{\pi_{\theta}}(s, a) \right) \right\|_{a = \pi_{\theta}(s)} \right] \leq B_{\theta} \mu^2 (p + 4)^2 H.
\]

This completes the proof. \( \square \)
C Proof of Lemma 3

First, by definition, it is true that

\[ \mathbb{E}[\|g_t\|^2] = \mathbb{E}\left[ \left\| \nabla_{\theta} \pi_{\theta_t}(s_t) \frac{\hat{Q}^+_t - \hat{Q}^-_t}{\mu} \right\|^2 \right], \]

where

\[ \hat{Q}^+_t = Q^{\pi_t}(\pm) + \frac{1}{N} \sum_{n=1}^{N} w^+_t \text{.} \]

By Cauchy-Schwarz, and by exploiting the above, we readily get

\[ \mathbb{E}[\|g_t\|^2] \leq B_0^2 \mathbb{E}\left[ \frac{Q^{\pi_t}(+)}{\mu} \left( \frac{Q^{\pi_t}(-)}{\mu} + \frac{1}{N} \sum_{n=1}^{N} w^+_t \right) \right] \]

\[ \leq B_0^2 \mathbb{E}\left[ \frac{Q^{\pi_t}(s_t, \pi_{\theta_t}(s_t) + \mu u)}{\mu} - Q^{\pi_t}(s_t, \pi_{\theta_t}(s_t)) \right]^2 \|u\|^2 \]

\[ + \frac{1}{N} \sum_{n=1}^{N} \|w^+_t - w^-_t\|^2 \|u\|^2 \] \quad (10)

For the first term on the right-hand side of (10), we have

\[ \mathbb{E}\left[ \frac{Q^{\pi_t}(s_t, \pi_{\theta_t}(s_t) + \mu u)}{\mu} - Q^{\pi_t}(s_t, \pi_{\theta_t}(s_t)) \right]^2 \|u\|^2 \leq \mathbb{E}[\|u\|^4] \leq L(p + 4)^2. \] \quad (11)

For the second term on the right-hand side of (10), we may write

\[ \mathbb{E}\left[ \frac{1}{N} \sum_{n=1}^{N} \frac{w^+_t - w^-_t}{\mu} \|u\|^2 \right] = \frac{1}{\mu^2 N^2} \mathbb{E}\left[ \sum_{n=1}^{N} \frac{w^+_t - w^-_t}{\mu} \|s_t, u, \theta_t, T_Q\|^2 \right] \]

\[ = \frac{1}{\mu^2 N^2} \mathbb{E}\left[ \|u\|^2 \left( \sum_{n=1}^{N} \frac{w^+_t - w^-_t}{\mu} \right)^2 \|s_t, u, \theta_t, T_Q\|^2 \right]. \]

Naturally, we need to focus on the (inner) conditional expectation above. By construction, it is true that, for every \( t \), the differences \( w^+_t - w^-_t \in \mathbb{N}^N \) are conditionally independent and identically distributed relative to \( s_t, u, \theta_t \) and \( T_Q \), and with zero mean. This implies that

\[ \mathbb{E}\left[ \sum_{n=1}^{N} \frac{w^+_t - w^-_t}{\mu} \|s_t, u, \theta_t, T_Q\|^2 \right] \]

\[ = N \mathbb{E}\left[ \|w^+_t - w^-_t\|^2 \|s_t, u, \theta_t, T_Q\|^2 \right], \]

\[ \leq N 2 \mathbb{E}\left[ (w^+_t)^2 + (w^-_t)^2 \|s_t, u, \theta_t, T_Q\|^2 \right] \]

\[ \leq N 4 \mathbb{E}\left[ \frac{1}{(1 - \gamma)^2} \right] = N \sigma^2, \]

where in the last line we have used Lemma 2 twice. As a result, we obtain that

\[ \mathbb{E}\left[ \frac{1}{N} \sum_{n=1}^{N} \frac{w^+_t - w^-_t}{\mu} \|u\|^2 \right] \leq \frac{\sigma^2}{\mu^2 N}. \] \quad (12)

since \( \mathbb{E}[\|u\|^2] \equiv p \). Combining (11) and (12), we end up with the uniform bound

\[ \mathbb{E}[\|g_t\|^2] \leq 2 B_0^2 \left( L(p + 4)^2 + \frac{\sigma^2 p}{\mu^2 N} \right), \]

thus completing the proof. \( \square \)
D Proof of Theorem 2

First, it is not hard to see that the stochastic ascend direction $q_t$ constructed by Algorithm 1 is an unbiased estimate of the quasi-gradient $\nabla J$. Indeed, with $s_t \sim \rho_{s_t}$, we may carefully write

$$E[g_t|\theta_t] = E\left[\nabla_{\theta_t} \pi_{\theta_t}(s_t) \frac{Q_t^e(s_t)}{\mu} - Q_t^e(s_t) \theta_t \right]$$

$$= E\left[\nabla_{\theta_t} \pi_{\theta_t}(s_t) \frac{Q_t^e(s_t, \theta_t, T_Q)}{\mu} - Q_t^e(s_t, \theta_t, T_Q) u_{s_t, \theta_t, T_Q} \right]$$

$$= E\left[\nabla_{\theta_t} \pi_{\theta_t}(s_t) \frac{Q_{s_t^e}(s_t, \pi_{\theta_t}(s_t))}{\mu} - Q_{s_t^e}(s_t, \pi_{\theta_t}(s_t)) u_{s_t, \theta_t} \right]$$

$$= E\left[\nabla_{\theta_t} \pi_{\theta_t}(s_t) \nabla_a Q_{s_t^e}(s, a) |_{a = \pi_{\theta_t}(s_t)} \right]$$

$$= \hat{\nabla} J(\theta_t).$$

Now, using the assumption that $J(\theta)$ is $L_J$-smooth, we have

$$J(\theta_{t+1}) \geq J(\theta_t) + (\theta_{t+1} - \theta_t)^\top \nabla J(\theta_t) - L_J \|\theta_{t+1} - \theta_t\|^2$$

From Algorithm 1, we have $\theta_{t+1} - \theta_t = \alpha q_{t}$. Let $E_t$ denote conditional expectation taken relative to history up to iteration $t - 1$. Then, by taking the expectation on both sides, we obtain

$E_t [J(\theta_{t+1})] \geq J(\theta_t) + \alpha \hat{\nabla} J(\theta_t)^\top \nabla J(\theta_t) - L_J \alpha^2 E_t \|[g_t]\|^2.$

Now add and subtract $\alpha \nabla J(\theta_t)^\top \nabla J(\theta_t)$ to the right hand side. By grouping terms, we may write

$E_t [J(\theta_{t+1})] \geq J(\theta_t) + \alpha \hat{\nabla} J(\theta_t)^\top \nabla J(\theta_t) + \alpha \|\nabla J(\theta_t)\|^2 - L_J \alpha^2 E_t \|[g_t]\|^2.$

Using Cauchy-Schwarz, we bound the term $(\hat{\nabla} J(\theta_t)^\top \nabla J(\theta_t))$ by $\|\nabla J(\theta_t)\| \cdot \|\nabla J(\theta_t)\|$. Further, because $J(\theta)$ is assumed to be $G_{J}$-Lipschitz, we have

$E_t [J(\theta_{t+1})] \geq J(\theta_t) - \alpha G_J \|\nabla J(\theta_t)\| + \alpha \|\nabla J(\theta_t)\|^2 - L_J \alpha^2 E_t \|[g_t]\|^2.$

Taking the total expectation, invoking Lemma 3 summing up until $T$, and dividing by $1/T$, we obtain

$$\frac{1}{T} \sum_{t=1}^{T} E \|\nabla J(\theta_t)\|^2 \leq \frac{\Delta_0}{\alpha T} + L_J \alpha (2B_0^2(p + 4)^2 L) + \frac{2B_0^2}{\mu^2 N} L_J \alpha^2$$

$$+ \frac{G_J}{T} \sum_{t=1}^{T} E \|\hat{\nabla} J(\theta_t) - \nabla J(\theta_t)\|, \tag{13}$$

where $\Delta_0 = J(\theta^*) - J(\theta_0)$ and $\theta^* \in \text{arg max} J(\theta)$.

Under Assumption 4, Theorem 1 implies that

$$\frac{1}{T} \sum_{t=1}^{T} E \|\nabla J(\theta_t)\|^2 \leq \frac{\Delta_0}{\alpha T} + L_J \alpha (2B_0^2(p + 4)^2 L) + \frac{2B_0^2}{\mu^2 N} L_J \alpha^2 + L_J B_0 \mu \sqrt{G}. \tag{14}$$

If, alternatively, Assumption 5 holds, then from 13 we use the pertinent result form Theorem 1 to obtain

$$\frac{1}{T} \sum_{t=1}^{T} E \|\nabla J(\theta_t)\|^2 \leq \frac{\Delta_0}{\alpha T} + L_J \alpha (2B_0^2(p + 4)^2 L) + \frac{2B_0^2}{\mu^2 N} L_J \alpha^2 + L_J B_0 \mu^2(p + 4)^2 H. \tag{15}$$
where $\Theta \subset \mathbb{R}^d$ is also assumed to be closed and convex. Below we present two approaches for deriving meaningful convergence rates.

**Extensions for constrained policy parameterizations:** In such a case, we may consider a projected gradient step in Algorithm 1 i.e.,
\[
\theta_{t+1} = \Pi_\Theta \{ \theta_t + \alpha g_t \},
\]
where $\Theta \subset \mathbb{R}^d$ is also assumed to be closed and convex. Below we present two approaches for deriving meaningful convergence rates.

**Noisy projection approach:** In this approach, we may expand the product $(\theta_{t+1} - \theta_t)^\top \nabla J(\theta_t)$ into two relevant terms as
\[
(\theta_{t+1} - \theta_t)^\top \nabla J(\theta_t) = (\theta_{t+1} + \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top \nabla J(\theta_t)
\]
\[
= (\Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top \nabla J(\theta_t)
\]
\[
+ (\theta_{t+1} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top \nabla J(\theta_t).
\]

For the first term, we invoke the key property [2, Lemma 1]
\[
(\Pi_\Theta \{ \theta + \alpha g \} - \theta)^\top g \geq \frac{1}{\alpha} \| \Pi_\Theta \{ \theta + \alpha g \} - \theta \|^2, \quad \forall (\theta, g) \in \Theta \times \mathbb{R}^d,
\]
yielding
\[
(\Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} - \theta_t)^\top \nabla J(\theta_t) \geq \frac{1}{\alpha} \| \theta_t - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} \|^2.
\]

For the second term, we may further expand as
\[
(\theta_{t+1} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top \nabla J(\theta_t)
\]
\[
= (\theta_{t+1} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top \nabla J(\theta_t)
\]
\[
+ (\Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top \nabla J(\theta_t),
\]
which implies that
\[
\mathbb{E}_t \{ (\theta_{t+1} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top \nabla J(\theta_t) \}
\]
\[
= (\mathbb{E}_t \{ \theta_{t+1} \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top \nabla J(\theta_t)
\]
\[
+ (\Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top \nabla J(\theta_t)
\]
\[
\geq -\| \nabla J(\theta_t) \| \| \mathbb{E}_t \{ \theta_{t+1} \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} \|
\]
\[
- \alpha \| \nabla J(\theta_t) \| \| \nabla J(\theta_t) - \nabla J(\theta_t) \|
\]
\[
\geq -GJ \| \mathbb{E}_t \{ \theta_{t+1} \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} \|
\]
\[
- \alpha GJ \| \nabla J(\theta_t) - \nabla J(\theta_t) \|.
\]

Consequently, we obtain the lower bound
\[
\mathbb{E}_t \{ (\theta_{t+1} - \theta_t)^\top \nabla J(\theta_t) \} \geq \frac{1}{\alpha} \| \theta_t - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} \|^2
\]
\[
- \alpha GJ \| \nabla J(\theta_t) - \nabla J(\theta_t) \|
\]
\[
- GJ \| \mathbb{E}_t \{ \theta_{t+1} \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} \|.
\]

Exploiting smoothness as in the unconstrained case discussed above, we end up with the complexity estimate
\[
\frac{1}{T} \sum_{t=1}^{T} \mathbb{E}_t \frac{1}{\alpha^2} \| \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} - \theta_t \|^2
\]
\[
\leq \frac{\Delta_0}{\alpha T} + L_J \alpha 2B_G^2 (p + 4)^2 L + \frac{2B_G^2}{\mu^2 N L_J \alpha p^2}
\]
\[
+ \frac{GJ}{T} \sum_{t=1}^{T} \mathbb{E}_t \| \nabla J(\theta_t) - \nabla J(\theta_t) \|
\]
\[
+ \frac{GJ}{\alpha T} \sum_{t=1}^{T} \mathbb{E}_t \| \mathbb{E}_t \{ \Pi_\Theta \{ \theta_t + \alpha g_t \} \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} \|.
\]
Note that, in the above, whenever it is actually the case that \( \theta_t + \alpha g_t \in \Theta \) conditioned on \( \theta_t \), it follows that (note that \( \Theta \) is closed convex)
\[
\Theta \ni \mathbb{E}_t[\Pi_\Theta \{ \theta_t + \alpha g_t \}] = \mathbb{E}_t[\theta_t + \alpha g_t] = \theta_t + \alpha \nabla J(\theta_t),
\]
which implies that
\[
\mathbb{E}_t[\Pi_\Theta \{ \theta_t + \alpha g_t \}] = \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \} = 0.
\]
This will happen when \( g_t \) is (or can be made) uniformly not too large relative to \( \theta_t \), and at the same time the stepsize \( \alpha \) is sufficiently small. Exactly such a behavior has been observed in our simulations.

**Mini-batch approach:** Alternatively, we may proceed to derive a slightly more pessimistic complexity estimate as
\[
(\theta_{t+1} - \theta_t)^\top \nabla J(\theta_t) = (\theta_{t+1} - \theta_t)^\top (\nabla J(\theta_t) - \hat{\nabla} J(\theta_t)) + (\theta_{t+1} - \theta_t)^\top \hat{\nabla} J(\theta_t).
\]
For the first term, Cauchy-Schwarz trivially gives
\[
(\theta_{t+1} - \theta_t)^\top (\nabla J(\theta_t) - \hat{\nabla} J(\theta_t)) \geq -\alpha \| g_t \| \| \nabla J(\theta_t) - \hat{\nabla} J(\theta_t) \|.
\]
For the second term, we may further expand as
\[
(\theta_{t+1} - \theta_t)^\top \hat{\nabla} J(\theta_t) = (\theta_{t+1} - \theta_t)^\top (\hat{\nabla} J(\theta_t) - g_t)
\]
where again invoking (16) yields
\[
(\theta_{t+1} - \theta_t)^\top g_t \geq \frac{1}{\alpha} \| \Pi_\Theta \{ \theta_t + \alpha g_t \} - \theta_t \|^2,
\]
whereas it also holds that
\[
(\theta_{t+1} - \theta_t)^\top (\hat{\nabla} J(\theta_t) - g_t) = (\Pi_\Theta \{ \theta_t + \alpha g_t \} - \theta_t)^\top (\hat{\nabla} J(\theta_t) - g_t)
\]
In regard, to the latter expression, it is then true that
\[
\mathbb{E}_t[(\theta_{t+1} - \theta_t)^\top (\hat{\nabla} J(\theta_t) - g_t)] = \mathbb{E}_t[(\Pi_\Theta \{ \theta_t + \alpha g_t \} - \Pi_\Theta \{ \theta_t + \alpha \nabla J(\theta_t) \})^\top (\hat{\nabla} J(\theta_t) - g_t)] + 0
\]
Combining everything, we get
\[
\mathbb{E}_t[(\theta_{t+1} - \theta_t)^\top \nabla J(\theta_t)] \geq \frac{1}{\alpha} \| \Pi_\Theta \{ \theta_t + \alpha g_t \} - \theta \|^2
\]

Now, note that we can write
\[
\frac{1}{\alpha^2} \mathbb{E}[||\Pi_\Theta \{\theta_t + \alpha \nabla J(\theta_t)\} - \theta_t||^2]
\]
\[
= \frac{1}{\alpha^2} \mathbb{E}[||\Pi_\Theta \{\theta_t + \alpha \nabla J(\theta_t)\} - \Pi_\Theta \{\theta_t + \alpha \nabla J(\theta_t)\} + \Pi_\Theta \{\theta_t + \alpha \nabla J(\theta_t)\} - \theta_t||^2]
\]
\[
\leq 2\mathbb{E}[||\nabla J(\theta_t) - \nabla J(\theta_t)||^2] + 2 \frac{1}{\alpha^2} \mathbb{E}[||\Pi_\Theta \{\theta_t + \alpha \nabla J(\theta_t)\} - \theta_t||^2]
\]
\[
= 2\mathbb{E}[||\nabla J(\theta_t) - \nabla J(\theta_t)||^2]
\]
\[
+ 2 \frac{1}{\alpha^2} \mathbb{E}[||\Pi_\Theta \{\theta_t + \alpha \nabla J(\theta_t)\} - \Pi_\Theta \{\theta_t + \alpha g_t\} + \Pi_\Theta \{\theta_t + \alpha g_t\} - \theta_t||^2]
\]
\[
\leq 2\mathbb{E}[||\nabla J(\theta_t) - \nabla J(\theta_t)||^2]
\]
\[
+ 4\mathbb{E}[||g_t - \nabla J(\theta_t)||^2]
\]
\[
+ 4 \frac{1}{\alpha^2} \mathbb{E}[||\Pi_\Theta \{\theta_t + \alpha g_t\} - \theta_t||^2].
\]
Finally, following the usual steps as above, we obtain the complexity estimate
\[
\frac{1}{T} \sum_{t=1}^{T} \frac{1}{\alpha} \mathbb{E}[||\Pi_\Theta \{\theta_t + \alpha \nabla J(\theta_t)\} - \theta_t||^2]
\]
\[
\leq \frac{2}{T} \sum_{t=1}^{T} \mathbb{E}[||\nabla J(\theta_t) - \nabla J(\theta_t)||^2] + 4 \frac{1}{T} \sum_{t=1}^{T} \mathbb{E}[||g_t - \nabla J(\theta_t)||^2]
\]
\[
+ \frac{\Delta_0}{\alpha T} + L_J \alpha 2B^2(\sigma + 4)^2 L + \frac{2B^2_\Theta}{\mu^2 N} L_J \alpha \sigma^2
\]
\[
+ \frac{1}{T} \sum_{t=1}^{T} \mathbb{E}[||g_t|| ||\nabla J(\theta_t) - \nabla J(\theta_t)||] + \frac{1}{T} \sum_{t=1}^{T} \mathbb{E}[||g_t - \nabla J(\theta_t)||^2],
\]
or, more compactly,
\[
\frac{1}{T} \sum_{t=1}^{T} \frac{1}{\alpha} \mathbb{E}[||\Pi_\Theta \{\theta_t + \alpha \nabla J(\theta_t)\} - \theta_t||^2]
\]
\[
\leq \frac{\Delta_0}{\alpha T} + L_J \alpha 2B^2(\sigma + 4)^2 L + \frac{2B^2_\Theta}{\mu^2 N} L_J \alpha \sigma^2
\]
\[
+ \frac{1}{T} \sum_{t=1}^{T} \mathbb{E}[||g_t|| ||\nabla J(\theta_t) - \nabla J(\theta_t)||] + \frac{2}{T} \sum_{t=1}^{T} \mathbb{E}[||\nabla J(\theta_t) - \nabla J(\theta_t)||^2]
\]
\[
+ \frac{5}{T} \sum_{t=1}^{T} \mathbb{E}[||g_t - \nabla J(\theta_t)||^2],
\]
This bound suggests that further variance reduction can be employed in order to make the term involving \(\mathbb{E}[||g_t - \nabla J(\theta_t)||^2] = \mathbb{E}[||g_t - \mathbb{E}[g_t|\theta_t]|^2]\) small, for instance by exploiting mini-batching, similar in spirit to [2]. However, this comes at the expense of significantly higher training overhead.

E  Complementary Numerical Results

In section[4] we presented the learning curves for our algorithm implemented on a navigation problem with and without system noise. We showed that in the case without noise, ZDPG enjoys a significant advantage over PG with baseline (PG-B), and of course standard PG. When the system has noise, the performance of ZDPG with asymmetric stochastic finite differences and PG-B are nearly identical,
whereas the symmetric version ZDPG-S is clearly advantageous. The main purpose of this section is to confirm that the advantage of ZDPG does not disappear as the noise in the system increases; in fact, it becomes even more drastic. We show this by comparing the learning curves on our navigation example for system noise variance $\omega = 0.01$ and $\omega = 0.1$, for different values of Monte-Carlo variance reduction ($N$), and policy evaluation rollout length ($T$).

In Figure 3, the evaluation rollout length is set to $T = 20$. The smoothing parameter for ZDPG-S is $\mu = 0.5$ for the $\omega = 0.01$ system noise case and $\mu = 0.6$ for the $\omega = 0.1$ system noise case. Analogously, for PG-B, we select action variance $\sigma = 0.25$ for both levels of system noise as this showed the most consistent performance throughout this line of experiments (by trial-and-error). For all simulations and for both methods, the learning rate was set to $\alpha = 10^{-7}$. Figure 3 (top) shows that, indeed, ZDPG-S remains advantageous over and consistently outperforms PG-B when the system noise is increased. More interestingly, ZDPG-S shows significant advantage over PG-B in terms of

Figure 3: Average reward per episode of length $T = 20$ with confidence bounds over 50 trials.

Figure 4: Average reward per episode of length $T = 100$ with confidence bounds over 50 trials.
noise resilience especially when there is no MC variance reduction at all (i.e. $N = 1$), which is a case of interest in most practical scenarios.

Figure[4] shows the learning curves for both methods when the evaluation length is set to $T = 100$. While the performance of both ZDPG-S and PG-B is more sensitive over such a longer evaluation horizon, the plots show that ZDPG-S experiences much more stability in solving the navigation problem for both levels of system noise. In contrast, PG-B becomes significantly unstable, resulting in trajectories that either do not necessarily reach the target, (see Fig[2]), or reach the target after a phase of prolonged, suboptimal wandering.

Again, we reiterate that the success of ZDPG comes from the non-heuristic use of deterministic policies, in contrast to random policies essential in log-trick-based standard (baseline) PG methods. Removing a level of randomness from the system allows the agent to reach a solution quickly and consistently.
