Predicting the afterglow duration in persistent phosphors: a validated approach to derive trap depth distributions

Olivier Q. De Clercq, Jiaren Du, Philippe F. Smet, Jonas J. Joos and Dirk Poelman

Persistent phosphors are increasingly investigated due to their potential applications in various fields, such as safety signage, dosimetry and in vivo imaging. These materials act as optical batteries that store and gradually release energy supplied during optical charging. As the energy is stored, or ‘trapped’, at specific defect sites in the host lattice, a clear understanding of the defects and trapping mechanisms in these materials is important for systematic improvement of their properties. Here, the thermoluminescence and afterglow properties of the near-infrared emitting persistent phosphor LiGa₅O₈:Cr³⁺ (LGO:Cr) are studied. This phosphor is used as a model system for illustrating a more general approach to reliably derive trap depth distributions in persistent luminescent and storage materials. The combination of the \( T_{\text{stop}} = T_{\text{max}} \) method with initial rise analysis is used to experimentally determine the presence of a broad distribution of trapping states. Computerized glow curve fitting is subsequently used to extract the relevant trapping parameters of the system in a rigorous, consistent manner, by fitting all the experimentally recorded data simultaneously. The resulting, single set of model parameters is able to describe all measured thermoluminescence and afterglow data and hence can be used to predict afterglow and storage properties of the phosphor under various conditions. The methods to analyze and describe the trap structure of the persistent phosphor LGO:Cr are straightforwardly applicable for other persistent and storage phosphors and result in a reliable determination of the relevant trapping parameters of a given material.

Introduction

Persistent phosphors are light-emitting materials that keep emitting light minutes to hours after excitation has ended.⁴ Aside from specific activator dopants in the crystalline host, which provide luminescence upon excitation, persistent phosphors also contain additional defects which can ‘trap’ charge carriers that are released from an excited state of the activator ion. These trapping defects can be deliberately added to the phosphor, or be intrinsically present. After being trapped at a crystal defect, the charge carriers can be released over the course of seconds to days, depending on the nature of the defects that are involved and the ambient temperature.

Divalent europium (Eu²⁺) is a popular activator ion for luminescent materials in general and persistent luminescent materials in particular.⁴ Its emission color can be tuned from the near-UV, across the visible spectral range up to red emission. In Eu-based systems, persistent luminescence is often induced or intensified by co-doping with a trivalent lanthanide ion, such as Nd³⁺ or Dy³⁺. A well-known example is SrAl₂O₄:Eu,Dy,⁴ which shows a characteristic green “glow-in-the-dark” emission that is used in various applications, ranging from toys and watch dials, to safety signage and road markings.⁴,⁶

Despite the high tunability of the Eu²⁺ ion, there is only a limited choice of host compounds that result in a deep red or near infrared (NIR) emission for Eu²⁺.⁷–⁹ This is unfortunate as red and near-infrared (NIR) emitting persistent phosphors have gained in interest and importance in recent years, due to their promise for bio-imaging applications.¹⁰–¹² The use of afterglow in in vivo imaging avoids a number of negative effects, such as damage to and autofluorescence from biological tissue, that are induced by the use of a continuous excitation source in traditional fluorescence imaging.¹³,¹⁴

The inability to use Eu²⁺ for this long-wavelength application has encouraged research and development into NIR persistent luminescent materials that are based on alternative activator ions,¹⁵ leading to the recent revival of Cr³⁺ based...
luminescent materials, such as ZnGa$_2$O$_4$:Cr$^{3+}$ or LiGa$_2$O$_4$:Cr$^{3+}$ in scientific literature.

Currently, the limited storage capacity of many persistent phosphors remains a significant drawback for their applicability in various fields. Understanding the trap structure of persistent phosphors and modifying it deliberately can lead to a large increase of the amount of energy that can be stored and subsequently be accessed ‘on demand’ by e.g. photostimulation, and hence, of the performance of these materials. The most widely used method for modifying the trap structure is codoping a phosphor with suitable elements that increase the amount of existing intrinsic defects or directly introduce additional trapping levels. Lanthanides are especially popular for this purpose, as their impurity level locations are fairly predictable, allowing to straightforwardly engineer materials with suitable trap depths. Alternatively, exploring variations in host composition can lead to the appropriate trap depth variation as well.

Usually, and especially with e.g. transition metals or main group ns$^2$ ions, these modifications are still done via a rather inefficient trial-and-error approach, as the studies for these elements provide empirical rules with more limited applicability, due to substantial uncertainties caused by their much stronger crystal field interactions and larger number of possible valence states, although recently considerable progress was made.

Therefore, by performing more in-depth studies rather than routine photoluminescence and afterglow experiments, one can obtain insight in the trap depth distribution of these persistent phosphors, which can be linked to the underlying defects and the (de)trapping mechanisms. Then, more targeted optimization of the desired properties is possible. The resulting experimental values and quantities can help to support more fundamental theoretical studies as well.

The technique that is commonly used to extract information about traps in persistent phosphors is thermoluminescence (TL). Here, after a charging step – typically with UV-vis light or ionizing radiation – the light output from a persistent phosphor is recorded while heating the sample with a (linear) heating rate. The resulting so-called glow curve can then be analyzed to see if there are various kinds of traps present in the phosphor and to extract trap depth energies for these different traps. One has to keep in mind that TL only provides indirect information about the traps and how they relate to the activator ions. Furthermore, although the theory behind TL is firmly established, the quantities that describe the TL properties of a given material, such as the trap depth energy and the escape frequency, are highly correlated, and one can thus not gain a complete understanding of the trap (depth) structure from only a single experiment. Especially when the TL glow curve is not characterized by a single, relatively narrow peak, one possibly deals with multiple trap depths, with a trap depth distribution or with higher-order kinetics of the detrapping process. This immediately leads to a large increase in the number of parameters for describing a single measured TL glow curve, which reduces the trustworthiness of derived parameter values, both via experimental techniques and computerized curve fitting. Great care and a combination of multiple techniques and experiments needs to be taken in order to avoid obtaining physically non-acceptable values.

In this work, we investigate the step-wise-annealed thermoluminescence and afterglow properties of the NIR-emitting persistent phosphor LiGa$_2$O$_4$:Cr$^{3+}$ (LGO:Cr). We show the presence of a broad distribution of trapping states, in contrast to the often assumed presence of discrete trapping states, and model the experimental data by a triple Gaussian distribution. All thermoluminescence and afterglow data can be simultaneously described by this model, using a single set of fitting parameters. We further use the model to predict afterglow properties at elevated temperatures, as relevant for instance in the case of in vivo imaging, and confirm the stability of the deep-lying traps for storage or for read-out by means of optical stimulation.

Materials & methods

Phosphor powder samples of LiGa$_2$O$_4$:Cr were made according to a solid state synthesis procedure, described in previous work. The Cr concentration was 1% of the Ga content. The samples had excellent phase-purity.

TL measurements were performed with the home-built setup described in Botterman et al. The detection system was modified by using a Thorlabs FDS1010 silicon photodiode connected to a Hamamatsu C9329 photosensor amplifier. Samples were excited for 10 min prior to each TL measurement, by use of the 254 nm emission line of a 3 W germicidal Hg-lamp (AquaEl). The employed heating rate was 0.25 K s$^{-1}$ for each measurement.

In previous work, thermal quenching (TQ) effects have been shown to have limited effect on the TL behavior of this type of Cr-doped persistent phosphors. There was a measured drop of the order of only 5% from the total initial luminescence at 200 °C. Therefore, no corrections for TQ have been applied in this work.

Fig. 1 shows the measurement procedure that was used to obtain the step-wise annealed TL data as a function of trap filling. The measurements were performed according to the McKeever $T_{stop}$-$T_{max}$ method, in which the charging step occurred at either $-10$ °C or $-60$ °C, followed by a thermal cleaning step up to an elevated temperature $T_{stop}$ (remaining there for 5 s), rapid cool down (initial rate of 0.5 K s$^{-1}$) and subsequent TL measurement.

Afterglow decay profiles were measured with a Centronic OSD100-5T silicon photodiode, calibrated in absolute radiometric units and connected to a Hamamatsu C9329 photosensor amplifier. Prior to afterglow measurements, the samples were excited for 5 min by 1000 lx light of an unfiltered Xenon arc lamp. This is the standard measurement procedure from industry to assess the performance of a given persistent phosphor.
Fig. 1 Experimental procedure for the TL measurements according to the McKeever \( T_{\text{stop}}-T_{\text{max}} \) method.\(^1\) Charging occurs at −10 °C or −60 °C, after which the sample is preheated to a varying, elevated temperature \( T_{\text{stop}} \). After this pre-heating step, the sample is cooled down again, followed by TL readout.

The temperature in the room during the afterglow recording was monitored and there was little variation in temperature values over the duration of the measurement (24.6 ± 1 °C). No real influence of this variation was found during simulations, so a constant temperature of 24.6 °C was used in the simulations.

Results & discussion

\( T_{\text{stop}}-T_{\text{max}} \) method and initial rise analysis

Measured TL glow curves for various, increasing values of \( T_{\text{stop}} \), starting at −50 °C and up to 130 °C, are shown in Fig. 2(a). Two main peaks, around 0 °C and 70 °C can be distinguished. There remains a non-zero TL signal above 220 °C as well. The high, continuous signal over the temperature range between −60 and 220 °C, combined with the gradual decrease in TL intensity and shift in temperature with increasing \( T_{\text{stop}} \), shows that it is very unlikely that the thermoluminescence is originating from well-defined, discrete trapping levels in the LGO phosphor, as is generally assumed.\(^2\)

Plotting the maximum of each glow peak (\( T_{\text{max}} \)) against \( T_{\text{stop}} \), gives rise to Fig. 2(c). According to McKeever,\(^1,4,3\) in the case of discrete trapping states in the host, a staircase-like \( T_{\text{stop}}-T_{\text{max}} \) plot should occur, with each plateau in the plot corresponding to a single trapping state. In contrast, a continuous set of close-lying states results in a linear relation between \( T_{\text{stop}} \) and \( T_{\text{max}} \). In Fig. 2(c), both effects are observed: there is a discrete jump in the \( T_{\text{stop}}-T_{\text{max}} \) plot at −10 °C, when the first peak in the glow curve is annealed. From 40 °C onwards, the plateau around 70 °C \( T_{\text{max}} \) evolves into a stronger linear increase in \( T_{\text{max}} \), pinpointing the presence of close-lying energy levels.

If the trap levels arise from localized defects, variations in the local symmetry or coordination of these defects – e.g. due to the presence of activator ions or other defects in the first few coordination shells – can cause a distribution of a trap energy level around a mean value. The two peaks in Fig. 2(a) indicate that in the case of LGO:Cr, at least two types of trap levels could be expected, possibly with a distribution in each of their energies.

A first estimate of the range of activation energies corresponding to the trap depth distribution in LGO:Cr can be provided by performing an initial rise analysis (IRA) on the TL data in Fig. 2(a).\(^4,4\) IRA is a popular technique to extract the activation energy from an experimentally recorded glow curve, because the errors on the obtained values are usually small and the analysis does not depend on the (de)trapping kinetics or the value of the ‘attempt-to-escape’ frequency factor.\(^3,8,45\)

IRA assumes that on the low-temperature side, the TL intensity can be approximated by:

\[
I(T) = C \exp\left(-\frac{E_a}{kT}\right)
\]  

where \( E_a \) is the initial rise activation energy, \( k \) is the Boltzmann constant and \( C \) is a proportionality constant. It was reported that equ (1) holds only for TL intensities up to 15% of the glow curve maximum intensity.\(^3,8,45\)

By plotting the TL data in an Arrhenius plot, we can then extract the activation energy \( E_a \) from the slope of the linear part of the curves. This is done in Fig. 2(b), which shows that the fits of equ (1) (in red) describe the data well. The resulting activation energies are plotted against \( T_{\text{stop}} \) in Fig. 2(d), and are listed in Table 2. The obtained energies range from ~0.55 eV to ~1.3 eV. It is worth noting that IRA in the case of trap depth distributions always gives the activation energy of the shallowest still-filled traps in the distribution under study.\(^4,4,46\) In contrast with the sudden jump in Fig. 2(c), the activation energies in Fig. 2(d) increase more gradually with \( T_{\text{stop}} \). This indicates strong overlap between the different components of the total trap depth distribution.

A theoretical model for the trap depth distribution

The experimental data in Fig. 2 indicate the presence of a very broad range of traps that are distributed around two mean energy values, corresponding to peak temperatures of 0 °C and 70 °C. An additional experiment to check the dose-dependence of the TL glow curves (charging for 1 to 10 min), did not show a prominent shift in the location of the maxima (not shown). Thus, we can assume the detrapping follows first order kinetics, meaning that retrapping of charge carriers after escape from a particular trap level is negligible.\(^38\)

We can describe the TL data and extract the relevant parameters by utilizing the following model. The expression for TL intensity in the presence of a continuous distribution of trapping states and first order kinetics is used:\(^3,8,4,4,47\)

\[
I(T) = \int_0^\infty N(E)f_0(E, T_{\text{stop}}) e^{-E/kT} \times \exp\left[-\frac{s}{\beta}\int_0^{T_{\text{stop}}} e^{-E/kT} dT \right] dE
\]

where

- \( s \) is the frequency factor. We assume that \( s \) is equal for all individual trap sub-distributions (see below).
- \( \beta \) is the employed linear heating rate of 0.25 K s\(^-1\).
- \( N(E) \) is the (continuous) density of trapping states as a function of energy. We assume \( N(E) \) to be a broad distribution, which consists
of three Gaussian functions with mean energies $E_{G,i}$ and widths of $s_{G,i}$ ($i = 1, 2, 3$). Fig. 3 shows such a trap depth distribution.

$$N(E) = \sum_{i=1}^{3} \left( N_{G,i} \exp \left( -\frac{(E - E_{G,i})^2}{2s_{G,i}^2} \right) \right)$$  

(3)

Gaussian distributions are a reasonable assumption when one expects a random incorporation of (multiple) defects. Other possible shapes for trap depth distributions that were already investigated in literature are uniform, exponential or binomial distributions among others.

- It has been shown that the integral over $T'$ in eqn (2) can be approximated by a series expansion, of which only the first two terms are retained:  

$$F(E, T) = \int_{f_0}^{T} e^{-E/kT'} dT' \approx kT^2 e^{-E/kT} \left( 1 - \frac{2kT}{E} \right)$$  

(4)

$f_0(E,T_{\text{stop}})$ is the filling factor of the distribution. This factor determines the fraction of trap levels that remain filled after the pre-heating step to $T_{\text{stop}}$. At higher values of $T_{\text{stop}}$ charge carriers that are trapped in shallow traps will have sufficient thermal energy to escape immediately.

There is no generally accepted expression available in literature for $f_0$. One possible way to take this into account is by calculating the fraction of trapped carriers that are released during the pre-heating step to $T_{\text{stop}}$, assuming saturated filling of the distribution during charging. The number of depleted carriers is then straightforwardly determined by taking the integral in eqn (4) up to $T_{\text{stop}}$:  

$$f_0(E, T_{\text{stop}}) = \exp \left( -\frac{E}{k} F(E, T_{\text{stop}}) \right)$$  

(5)

The effect of $f_0$ on the filling of the trap depth distribution is shown in Fig. 3.
- In the integration over the energy (eqn (2)), the limits of integration can be narrowed to the interval where traps are present. Here, 0.1 eV and 4.0 eV are chosen for $E_1$ and $E_2$ respectively.

- In order to get the best agreement between model and data, it was necessary to introduce a correction to the nominal, experimental temperature $T_{\text{stop}}$ for each experiment, as a correction factor $\Delta T$. This is due to the fact that the quenching rate for the cooldown step following the preheating to $T_{\text{stop}}$ is not infinite. In other words, the TL signal will deplete naturally between the cooldown and the recording of the final TL glow curve, effectively introducing an offset between the experimental value for $T_{\text{stop}}$ and what is obtained from the data. It was found that a single $\Delta T$ is able to account for this complication for all experiments, adding an additional parameter to the model: $T_{\text{stop}} = T_{\text{stop}} + \Delta T$.

This leads to the final expression for our TL model:

$$I(T) = \int_{E_1}^{E_2} \left[ \sum_{i=1}^{2} \left( N_{G_i} \exp \left( -\frac{(E - E_{G_i})^2}{2\sigma_{E_i}^2} \right) \right) e^{-E/kT} \times \exp \left( -\frac{s kT^2}{E} e^{-E/kT} \left( 1 - \frac{2kT}{E} \right) \right) \times \exp \left( -\frac{s kT_{\text{stop}}^2}{E} e^{-E/kT_{\text{stop}}} \left( 1 - \frac{2kT_{\text{stop}}}{E} \right) \right) \right] dE$$

(6)

We can numerically integrate eqn (6) and subsequently fit it to the experimental data. This is done by minimizing the sum over the ‘Figure-of-Merit’ (FOM) values for each of the experimental curves\textsuperscript{54,55}

$$\sum_{i=1}^{n} \text{FOM}_{T_{\text{stop}}} = \frac{\sum_{i=1}^{n} \sum_{p} \left| y_{\text{fit}} - y_{\text{exp}} \right|}{\sum_{i=1}^{n} \sum_{p} y_{\text{fit}}}$$

(7)

while varying the parameters $E_{G_i,0}$, $\sigma_{E_i,0}$, $N_{G_i}$, and $\Delta T$ defined in eqn (6). The summation over $p$ extends over all individual data points in the experiments. A Nelder–Mead Simplex method\textsuperscript{56,57} for finding the minimum of eqn (7), was used for the optimization.

As the TL profiles are normalized, one of the pre-factors, $N_{G_1,2}$ (eqn (3)), can also be eliminated from the fit, keeping only two ratios $R_1$ and $R_3$:

$$R_1 = N_{G_1}/N_{G_2},$$

$$R_3 = N_{G_3}/N_{G_2},$$

with respect to the amplitude of sub-distribution 2, which causes the main TL peak from charging at room temperature.

It is an important aspect of the fitting process that all TL glow curves, measured for the different $T_{\text{stop}}$ values, are fitted simultaneously with a unique set of parameters, not only restricting the number of used parameters to 9 – in addition to the choice of frequency factor $s$ (see below) – but also improving the credibility of the TL model. Ultimately, we end up with a single set of trapping parameters that describe all 19 experimental TL glow curves. The results are shown in Fig. 4 for selected TL glow curves. The obtained fitting parameters are given in Table 1.

Fig. 4 shows good agreement between data and model, with FOM values below 4% for most fits (see Table 2) and the plotted relative errors between experiment and fit are shown. All relative errors between the fits and data are below 10% and no large systematic discrepancies occur. The FOM-values for all fitted curves are below 4% (Table 2), corresponding to a good fit of the prominent features of the glow curves. For clarity, presentation of simulation results was split between (a) glow curves with $T_{\text{stop}}$ ranging from $-50^\circ\text{C}$ to $-20^\circ\text{C}$, and (b) glow curves with $T_{\text{stop}}$ ranging from $20^\circ\text{C}$ to $90^\circ\text{C}$.

![Graphs showing TL glow curves](image)

### Table 1. Extracted fit parameters to describe the data in Fig. 4. The value for the frequency factor $s$ was kept constant at $1.0 \times 10^{12}$ s\textsuperscript{-1}. Numerical indices for the parameters correspond to the different sub-distributions shown in Fig. 3.

| $E_{G,1}$ (eV) | $\sigma_{E,1}$ (eV) | $R_1$ | $E_{G,2}$ (eV) | $\sigma_{E,2}$ (eV) | $R_2$ | $E_{G,3}$ (eV) | $\sigma_{E,3}$ (eV) | $R_3$ | $\Delta T$ (°C) |
|---------------|-----------------|-------|---------------|-----------------|-------|---------------|-----------------|-------|-----------------|
| 0.72          | 0.06            | 1.08  | 0.94          | 0.13            | 1.19  | 0.20          | 0.13            |        | 4.83            |
of 0.72 eV, 0.94 eV and 1.19 eV. The defects that result in the second sub-distribution (centered around 0.94 eV) are the main cause of the persistent luminescence properties of LGO:Cr at room temperature, as is also shown in Fig. 7 and 8.

The obtained mean energies for the Gaussian sub-distributions, $E_{G,i}$, are close to the experimental initial rise energies, but lie consistently higher than those, up to $T_{\text{stop}} > 80$ °C (Table 2). This is expected as the obtained $E_A$ should give the energy corresponding to the shallowest filled traps in the distribution.

We used our simulated data set of glow curves to additionally perform IRA on them, in order to compare obtained ‘simulated initial rise energies $E_{A-S}$’ with the experimental values (Table 2). The Arrhenius plot and $T_{\text{stop}}$-$E_{A-S}$ plots are shown in Fig. 5.

Note that the value for the frequency factor $s$ scales the other values for the energy parameters in the model, showing a positive correlation coefficient of at least 0.67 between $s$ and each of the individual mean energy parameters $E_{G,i}$. The resulting $E_{G,i}$ for each value of $s$ after running the fit procedure again, are given in Table 3.

Additionally, we found a slight dependence of both the heating rate $\beta$ and the frequency factor $s$ on the simulated $E_{A-S}$ values. This can be explained by the effect of the filling factor $f_0(E,T_{\text{stop}})$ in the expression for the TL intensity (eqn (6)) that was used to simulate the temperature-annealed set of glow curves, which depends both on $\beta$ and $s$. The shift in values was less than 0.1 eV for each of the obtained $E_{A-S}$ for $\beta$ between 0.08 and 1.0 K s$^{-1}$, and for $s$ between $10^{11}$ and $10^{13}$ s$^{-1}$, when keeping the fit parameters as listed in Table 1. Within this error, the values for $E_A$ and $E_{A-S}$ largely correspond with each other.

Because of this large correlation and the influence of $f_0$ on the $E_{A-S}$, the frequency factor $s$ was kept constant at a value of $1.0 \times 10^{12}$ s$^{-1}$ during the final fitting procedure. This value ultimately resulted in the lowest FOM values for the fitted glow curves. Furthermore, the simulated $E_{A-S}$ for this value of $s$ corresponded best with the experimentally derived energies. This value for $s$ is physically sound and consistent with the frequencies of vibrational modes around 500 cm$^{-1}$ ($\approx 1.5 \times 10^{13}$ Hz) that were measured for LGO.

**Modeling the afterglow data**

To further verify the above results from the TL data, we use the obtained parameters for the trap depth distribution shown in Table 1 as input for a simulation of the afterglow profile of LGO, according to the following expression for expected...
afterglow in the presence of a trap depth distribution and occurrence of first order kinetics: 

\[ I(t) = \int_0^\infty sN(E)f_0(E, T_{\text{stop}})e^{-E/kT} \times \exp\left[-st\frac{E}{kT}\right]dE \]

The results are shown in Fig. 6. There is an excellent agreement between the model and afterglow data, from the first seconds up to 15 h after ending the excitation. The good correspondence indicates that the parameters that were obtained from TL experiments are able to reliably describe the trapping and detrapping dynamics of this phosphor. Hence, the derived trap depth distribution is able to describe isothermal decay as well as the influence of varying temperature during the thermoluminescence glow curves, giving predictive power to the derived trap depth distribution.

**Contribution of trap depth distribution to afterglow**

In order to assess which fraction of the trap depth distribution contributes to the room-temperature afterglow, we performed a TL experiment in which we kept a sample in the dark for several hours after charging. These data are given as the black curves in Fig. 7(a). This figure shows the loss of TL signal over a period of 15 h, after a 10 min charging step at 20 °C with 254 nm UV light. The loss in signal is about 47%, which can be due to afterglow, but also non-radiative decay and quenching.

We checked if our model can describe this depletion of stored energy. In order to do this, we need to add an additional, time-dependent filling factor \( f_s(E, t_{\text{storage}}, T_{\text{storage}}) \) to eqn (6):

\[ f_s(E, t_{\text{storage}}, T_{\text{storage}}) = \exp\left[-st_{\text{storage}}e^{-E/kT_{\text{storage}}}\right] \]

Comparing the expected trapped depletion from our model (red curves) with the experimental data, we again see good agreement between the two. The simulated glow curve for 15 h of storage lies higher than the measured depleted one. The difference between the simulated and measured glow curve is only 5%, which can be due to the mentioned non-radiative decay routes or the possibility of a decay route not described by first order decay, e.g. a tunneling mechanism. The influence of these effects must be small, because the measured afterglow is almost perfectly reproduced by the model (Fig. 6). This points to the occurrence of a limited non-radiative quenching as an additional depletion mechanism.

Our developed model can now be used to predict the remaining fraction of traps after longer storage times than measured. This is shown in Fig. 7(b). At room temperature, deep traps keep on depleting continuously, but the rate of depletion slows down after 20 h of storage in the dark, with 32% of the initially filled traps still remaining after 168 hours. A large fraction of the filled traps are thus not accessible at room temperature.

The influence of the storage temperature on the trap depletion is shown in Fig. 7(c), where the higher the storage temperature, the bigger the depletion of the filled TL glow curve. Still, even at 40 °C, 26% of traps remain filled after 24 h and 17% after 168 hours. This gives opportunities to use other techniques to empty these deeper traps, e.g. optically stimulated luminescence (OSL) in order to increase the light output of the LGO:Cr phosphor.

Conversely, the model shows that most of the stored energy is depleted by yielding afterglow. Since the afterglow at room temperature is accurately described by the model, we can estimate the actual afterglow intensity at higher temperatures by only varying the input temperature in eqn (8). The results are shown in Fig. 8. Here, we plot the afterglow curves when only the sub-distributions 2 and 3 are initially filled; a situation comparable to charging at 20 °C. The deeper traps become accessible at higher afterglow temperature, increasing the intensity twofold after 10^5 seconds of simulated afterglow time. The inset shows the depletion of the filled traps after 10^5 seconds. Of course at 40 °C, more traps are emptied faster, but an appreciable fraction of filled traps remains, helpful for access by OSL in in vivo experiments. These simulations immediately show the potential of the phosphor LGO:Cr in bio-imaging applications.

**General discussion & perspectives**

Several methods for retrieving the main trapping parameters of a measured glow curve exist in literature. All of these rely on...
assumptions and approximations, some of them well-founded, others more speculative. For this reason, it is not expected that only a single technique can give a full overview of the underlying electronic structure of the trapping defects, or the dynamics of the trapping and detrapping processes that are at play in a given TL material.65

Furthermore, because of the high correlation between the different trapping parameters such as trap depth and escape frequency (see Table 3), one cannot expect to gain a complete understanding of the trapping structure of a given persistent phosphor from only a single TL measurement.

In this work, we used the combination of the initial rise technique and computerized glow curve fitting on a large set of step-wise annealed TL data, in order to obtain a reliable trap depth distribution in the case of the persistent phosphor LGO:Cr, enabling a more thorough understanding of how the presence of trapping defects alter its physical properties. Notably, the obtained trap distribution can be used to simulate the expected afterglow profile, which reproduces the experimental profile in an excellent way. This information about the trap depth distribution can immediately be used to estimate the performance of the phosphor in various conditions.

The initial rise method is a commonly used experimental TL technique because it is not very time-consuming, easily applied and gives a value for the activation energy in the case of a single trapping state to high accuracy.45 When there is a distribution of trap depths present, it provides the value of the lowest occupied trap levels in the filled part of the distribution,44 as was also shown here. Via the use of the $T_{\text{stop}}-T_{\text{max}}$ method,
the initial rise analysis on a series of step-wise annealed TL curves does reveal whether or not there is a distribution present in the material.\textsuperscript{18} Information about the frequency factor is not obtainable via IRA, but the resulting energy values should be independent of the values of $s$. Therefore, the energy values obtained from IRA are good starting estimates, to compare with more intricate methods.

The experimental glow curves are analyzed further by using computerized curve fitting according to eqn (6) and (7), where the underlying assumptions are limited in comparison with other, more empirical techniques such as Hoogenstraaten or peak shape methods.\textsuperscript{60,62} However, overfitting experimental data by use of too many fitting parameters is an important concern and needs to be avoided.\textsuperscript{43} Therefore, a model should be able to describe multiple experiments at once, thereby putting more restrictions on the fitting procedure and giving more physically meaningful values as a result.\textsuperscript{66}

In this sense, the fact that we can describe all TL data and that the results allow to accurately simulate the independently recorded afterglow data, shows that the model of a broad trap depth distribution (eqn (3)) is a valid one for the persistent phosphor LGO:Cr. This fitting procedure can be straightforwardly transferred to the analysis of TL and afterglow experiments on different materials, possibly clarifying the current ambiguity of empirical parameters used to describe the behaviour of persistent and storage phosphors.

In the case of LGO:Cr, the presence of traps over such a broad energy range, extending over more than 1 eV in width, shows that LGO can be used in different temperature conditions. For applications, charging will typically be performed around room temperature and higher, and it is expected that the shallow traps in the material, corresponding to the glow peak at 0 °C, do not influence the long-term persistent luminescence, as shown in Fig. 7 and 8. However, our model can be used to predict the afterglow properties of the material for higher temperature conditions as well – in particular normothermia (\textit{i.e.} normal human body temperature) – and shows that LGO:Cr is useful for \textit{in vivo} imaging applications (Fig. 8).

The nature of the traps responsible for the trapping in LGO:Cr remains elusive, although this work provides some new insights. Looking at the derived trap distribution with its multiple components, it is probable that multiple defects, rather than a single well-defined trapping center can act as traps. It is believed that chromium ions are responsible for self-trapping.\textsuperscript{21,67} The measured double banded TL signal in Fig. 2(a) which extends over a broad temperature range was also observed in other, similar NIR persistent phosphors such as LaAlO$_2$:Mn$^{4+}$ or Gd$_3$Al$_5$Ga$_2$O$_{12}$:Cr$^{3+}$\textsuperscript{34,68} which have different host structures than the inverse spinel LiGa$_3$O$_8$. Therefore, the similar shape of the TL glow curves in different hosts could indicate that the recorded signal is partially due to the chromium activator itself. However, separating the contribution of Cr ions from other defect contributions is not straightforward, as variation in Cr content necessarily leads to a variation in luminescence output and quenching effects, and possibly a change in the intrinsic defect concentration.\textsuperscript{18} To identify the nature of the traps, it is likely that highly accurate theoretical techniques are required to complement the experimental data.\textsuperscript{18}

To aid the comparison between both, reliable analysis techniques with a minimum of parameters and a straightforward physical interpretation are desirable, as was demonstrated here for the NIR persistent phosphor LGO:Cr\textsuperscript{35}.

Conclusions

In this work, the thermoluminescence and afterglow properties of the NIR-emitting persistent phosphor LiGa$_3$O$_8$:Cr$^{3+}$ (LGO:Cr) were studied. A combination of McKeever’s $T_{\text{stop}}$-$T_{\text{max}}$ method with initial rise analysis showed the presence of a broad distribution of trapping states in LGO:Cr between 0.55 and 1.3 eV. Of these, the states with energies between 0.85 eV and 1.02 eV are mainly accessible when charging the phosphor at room temperature.

We modelled the trap structure of the LGO persistent phosphor in a rigorous manner by limiting the number of fitting parameters and increasing the experimental data set used for the fit procedure. The traps in the phosphor can be described in terms of a total trap depth distribution that consists of three Gaussian sub-distributions. Both experimental TL and afterglow decay data are well-described by the model. The results show that the afterglow at room temperature is arising from a broad trap sub-distribution with a trapping energy around 0.94 eV. We use the model to simulated expected afterglow behaviour at elevated temperatures to show the potential of using LGO:Cr for long term \textit{in vivo} imaging.

The model can be used to predict the stability of the deep-lying traps over longer periods of storage and at other storage temperatures than room temperature. We found that 32% of traps remain filled after storage for 168 hours at 20 °C and 17% at 40 °C. This large fraction of stable traps opens up possibilities for applications at elevated temperatures, dosimetry or use of optical stimulation to deplete the remaining trapping states on demand.

The methods to analyze and describe the trapping structure of the persistent phosphor LGO:Cr are straightforwardly applicable to other persistent and storage phosphors. With this approach, it is expected that the relevant trapping parameters of a given material can be determined more accurately, thus leading to better prediction and evaluation of the performance under various conditions.

Conflicts of interest
