Andreev reflection in two-dimensional topological insulators with either conserved or broken time-reversal symmetry

We investigate Andreev reflection in two-dimensional heterojunctions formed by a superconductor in contact with a topological insulator ribbon either possessing or breaking time-reversal symmetry. Both classes of topological insulators exhibit perfect Andreev reflection, robust against disorder. This is assigned to topologically protected edge states. In the time-reversal symmetric case we show that doping one of the ribbon edges with magnetic impurities suppresses one Andreev channel, while no such suppression is seen in the broken symmetry situation. Based on this observation we suggest a transport experiment able to distinguish between the two types of topological insulators.

PACS numbers:

Topological insulators (TI) are a novel class of materials, which have been intensively investigated in the past few years [1, 2]. They come in two varieties, $Z_2$ insulators, which preserve time-reversal symmetry, and Chern insulators, which do not. At present a variety of materials have been found to exhibit the time-reversal symmetric topological phase [3, 4]. In contrast, although there are several theoretical proposals for constructing a Chern insulator [4, 5], none has been reported to date and the experimental quest continues. Also it is intriguing the possibility of interfacing $Z_2$ insulators with superconductors (SCs). This interface has been predicted to host Majorana fermions, with possible applications in topological quantum computing [6].

A metal/superconductor interface may reflect an incident electron from the metal as a positively charged hole with opposite spin, while a Cooper pair is formed in the superconductor. This electron-hole conversion is known as Andreev reflection [10] and has long served as a useful probe for spin-polarized currents [11]. As topological insulators in general sustain edge states with a well-defined spin, the Andreev reflection technique appears to be particularly suited to study edge states scattering in topological insulators.

Recently there have been several interesting suggestions for turning the prototypical two-dimensional material graphene into a topological insulator. As far as the time-reversal symmetry broken case is concerned, Qiao et al. have shown, by means of first principles calculations, that Fe atoms adsorbed on graphene open up a band-gap in the bulk and yield a non-zero Chern number for the valence band [8]. In another ingenious proposal Weeks et al. suggested to dope graphene with non-magnetic heavy adatoms in order to stabilize a time-reversal symmetric topological insulating phase [12]. In light of these promising developments, we have decided to study Andreev reflection in two-dimensional topological insulator-superconductor junctions.

We consider a two-dimensional topological insulator ribbon realized on a honeycomb lattice with zig-zag edge geometry, as shown in Fig. 1. The region to the right (SC region) is proximity coupled to a superconducting electrode, while the region on the left (TI region) is the topological insulator. The electron and hole spectra are described at the mean-field level by the Bogoliubov-de Gennes equation [13],

$$
\begin{pmatrix}
H - E_F & \Delta \\
\Delta^* & E_F - THT^{-1}
\end{pmatrix}
\begin{pmatrix}
u \\
v'
\end{pmatrix}
= \varepsilon
\begin{pmatrix}
u \\
v'
\end{pmatrix},
$$

where $u$ and $v$ are the wave-functions for electrons and holes, respectively. $H$ is the single-particle Hamiltonian for the topological insulators, $T$ is the time-reversal operator, $\Delta$ is the pairing potential and $E_F$ is the Fermi level. In the left region (TI) the pairing potential is set to zero, i.e., there is no superconductivity. In the right region (SC) a finite constant pairing potential exists due to the proximity with a superconducting electrode.

We use the Kane-Mele model [14] as singlet microscopic Hamiltonian for the time reversal symmetric ($Z_2$) topological insulator. This reads

$$H_{KM} = t \sum_{<ij>} c_{ij}^\dagger c_j + \lambda \sum_i c_i^\dagger c_i + it_2 \sum_{<ij>} \nu_{ij} c_i^\dagger \sigma^z c_j.
$$

Here the first term is just the nearest-neighbour hopping with strength $t$, where the spin indices of the creation, $c_i^\dagger$, and annihilation, $c_i$, operators have been omitted. The second term represents a staggered sub-lattice potential, i.e., the $A$ type sub-lattice has an onsite energy $\lambda (\xi = +1)$, while the $B$ sub-lattice has onsite energy $-\lambda (\xi = -1)$. The last term describes second nearest-neighbour hopping with strength $t_2$ and it is purely imaginary ($t_2$ is real and $i = \sqrt{-1}$). Furthermore $\nu_{ij}$ is equal to $+1$ for anti-clockwise hopping and to $-1$ for clockwise. Here $\sigma^z$ is the $z$-component Pauli matrix describing the electron’s spin. The last term can be thought as a mirror-symmetric spin-orbit interaction, since it couples the orbital motion of the electrons to their spins.

For the time-reversal symmetry broken case we use a spinfull version of the Haldane model [15], proposed by...
Chen et al. \cite{16} (from now on the spin-Haldane model, SH). The single particle Hamiltonian reads

\[ H_{\text{SH}} = t \sum_{\langle ij \rangle} c_i^{\dagger} c_j + \gamma \sum_i c_i^{\dagger} \sigma_i^z c_i + i \beta(\gamma) \sum_{\langle \langle ij \rangle \rangle} \nu_{ij} c_i^{\dagger} c_j , \]

where the second term is the exchange field with strength \( \gamma \), i.e., it represents Zeeman coupling. In addition to spin, also the orbital angular momentum of the electron, \( \nu_{ij} \), is coupled to the exchange field. Following Chen et al. \cite{16} we approximate \( \beta(\gamma) \approx \beta \text{sgn}(\gamma) \), and choose \( \beta \) to be negative. This parameter set describes a diamagnetic sign for both the spins, as opposed to that in \( \gamma \)

\[ \langle \langle ij \rangle \rangle \]

where \( \nu_{ij} \) is the coupling matrix between cells \( \nu_{ij} \) is the coupling matrix between the scattering region and the left-hand side (right-hand side) contact. Then, the retarded Green’s function, \( g_s \), is calculated iteratively from the following equation \cite{18}:

\[ g_s = [(E + i0^+)I - H_0 - H_1 g_s H_1^\dagger]^{-1} , \]

where \( H_0 \) is the Hamiltonian describing the electrodes unit cell and \( H_1 \) is the coupling matrix between cells (note that in our tight-binding formulation the Hamiltonian of the ribbon has a tri-diagonal form). The self-energy matrices are given by \( \Sigma_{L,R} = H_{L,R} g_s H_{L,R}^\dagger \), where \( H_L \) (\( H_R \)) is the coupling matrix between the scattering region and the left-hand side (right-hand side) contact. Then, the retarded Green’s function, \( G^r \), for the scattering region of Hamiltonian \( H_{\text{SC}} \) is obtained as \( G^r = [(E + i0^+)I - H_{\text{SC}} - \Sigma_L - \Sigma_R]^{-1} \). The scattering region comprises the SC/TI interface and a portion of the electrodes. Finally, the total transmission is simply \( T(E) = \text{Tr}(\Gamma_L G^r \Gamma_R G^r) \), where \( \Gamma_{L,R} \) are the broadening matrices \( \Gamma_{L,R} = i[\Sigma_{L,R} - \Sigma_{L,R}^\dagger] \). Furthermore, the normal transmission coefficient from the \( n \)-th terminal to the \( m \)-th one is obtained as \( T_{n,m} (E) = \text{Tr}(\Gamma_{n\sigma} G^r_{\sigma\sigma} \Gamma_{m\sigma} G^r_{\sigma\sigma}^\dagger) \), while the Andreev reflection coefficient is calculated as

\[ R_{n,m,s,\bar{\sigma}}^A (E) = \text{Tr}(\Gamma_{n\sigma} G^r_{\sigma\epsilon} \Gamma_{m\bar{\sigma}} G^r_{\epsilon\bar{\sigma}}^\dagger) \]

where \( \sigma = (\uparrow, \downarrow) \) and \( \bar{\sigma} = (\downarrow, \uparrow) \) are the spin indices. Thus \( R_{n,m,s,\bar{\sigma}}^A \) describes an incident electron from terminal \( n \) being reflected as an opposite spin hole into terminal \( m \).

We begin our analysis by calculating \( R^A \) as a function of energy, which is shown in figures \( \text{(a) and (b)} \) respectively for the Kane-Mele and spin-Haldane model. Henceforth, we set the nearest neighbor hopping \( t = 1 \) and measure all the energies in units of \( t \). Furthermore we fix the number of sites along the ribbon width to be \( n_y = 18 \). The insets of Fig. \( \text{2} \) show the bandstructure for the two models calculated in this strip geometry. In the bulk gap there exist gapless edge modes, a single pair on each edge. For the \( H_{\text{KM}} \) Hamiltonian, these are opposite spin Kramer’s pairs, while for \( H_{\text{SH}} \), there are two left-movers (one for each spin) at one edge and two right-movers at the other, exactly like integer Quantum Hall states. We find that for both these cases, the edge modes lead to a perfect Andreev reflection for electrons with energy smaller than the superconducting gap. In fact, in both cases the edge modes are perfectly Andreev reflected. Normal reflection, where an incident particle is reflected back without being converted into its antiparticle, is completely suppressed for the edge states as long as the Fermi energy lies in the bulk gap, as we have verified numerically. These findings are consistent with recent theoretical and experimental studies for time-reversal symmetric topological insulators \cite{19,20}.

We use the ballistic Landauer-Büttiker scheme \cite{17} for calculating the transmission across the system. The self-energy matrix \( \Sigma_L (\Sigma_R) \) for the left-hand side (right-hand side) contact is obtained by using the electrodes’ surface Green’s function, \( g_s \). This is calculated iteratively from the following equation \cite{18}:

\[ g_s = [(E + i0^+)I - H_0 - H_1 g_s H_1^\dagger]^{-1} , \]

where \( H_0 \) is the Hamiltonian describing the electrodes unit cell and \( H_1 \) is the coupling matrix between cells (note that in our tight-binding formulation the Hamiltonian of the ribbon has a tri-diagonal form). The self-energy matrices are given by \( \Sigma_{L,R} = H_{L,R} g_s H_{L,R}^\dagger \), where \( H_L \) (\( H_R \)) is the coupling matrix between the scattering region and the left-hand side (right-hand side) contact. Then, the retarded Green’s function, \( G^r \), for the scattering region of Hamiltonian \( H_{\text{SC}} \) is obtained as \( G^r = [(E + i0^+)I - H_{\text{SC}} - \Sigma_L - \Sigma_R]^{-1} \). The scattering region comprises the SC/TI interface and a portion of the electrodes. Finally, the total transmission is simply \( T(E) = \text{Tr}(\Gamma_L G^r \Gamma_R G^r) \), where \( \Gamma_{L,R} \) are the broadening matrices \( \Gamma_{L,R} = i[\Sigma_{L,R} - \Sigma_{L,R}^\dagger] \). Furthermore, the normal transmission coefficient from the \( n \)-th terminal to the \( m \)-th one is obtained as \( T_{n,m} (E) = \text{Tr}(\Gamma_{n\sigma} G^r_{\sigma\sigma} \Gamma_{m\sigma} G^r_{\sigma\sigma}^\dagger) \), while the Andreev reflection coefficient is calculated as

\[ R_{n,m,s,\bar{\sigma}}^A (E) = \text{Tr}(\Gamma_{n\sigma} G^r_{\sigma\epsilon} \Gamma_{m\bar{\sigma}} G^r_{\epsilon\bar{\sigma}}^\dagger) \]

where \( \sigma = (\uparrow, \downarrow) \) and \( \bar{\sigma} = (\downarrow, \uparrow) \) are the spin indices. Thus \( R_{n,m,s,\bar{\sigma}}^A \) describes an incident electron from terminal \( n \) being reflected as an opposite spin hole into terminal \( m \).

We begin our analysis by calculating \( R^A \) as a function of energy, which is shown in figures \( \text{(a) and (b)} \) respectively for the Kane-Mele and spin-Haldane model. Henceforth, we set the nearest neighbor hopping \( t = 1 \) and measure all the energies in units of \( t \). Furthermore we fix the number of sites along the ribbon width to be \( n_y = 18 \). The insets of Fig. \( \text{2} \) show the bandstructure for the two models calculated in this strip geometry. In the bulk gap there exist gapless edge modes, a single pair on each edge. For the \( H_{\text{KM}} \) Hamiltonian, these are opposite spin Kramer’s pairs, while for \( H_{\text{SH}} \), there are two left-movers (one for each spin) at one edge and two right-movers at the other, exactly like integer Quantum Hall states. We find that for both these cases, the edge modes lead to a perfect Andreev reflection for electrons with energy smaller than the superconducting gap. In fact, in both cases the edge modes are perfectly Andreev reflected. Normal reflection, where an incident particle is reflected back without being converted into its antiparticle, is completely suppressed for the edge states as long as the Fermi energy lies in the bulk gap, as we have verified numerically. These findings are consistent with recent theoretical and experimental studies for time-reversal symmetric topological insulators \cite{19,20}.

![Diagram](TI_SC.png)

FIG. 1: Setup for calculating the two terminal transmission. Region SC is proximity coupled to a superconducting electrode while region TI is the topological insulator described by the two chosen single particle models. The rectangle marks the region at the TI/SC interface where disorder is introduced.

![Diagram](Bandstructure.png)

FIG. 2: Andreev reflection coefficient for (a) \( Z_2 \) and (b) Chern insulators showing perfect Andreev reflection for electron energies smaller than the superconducting gap. The insets show the bandstructure for the two models solved in a ribbon geometry. Here we choose \( t_2 = 0.33, \lambda/t_2 = 2.0, \gamma = 0.20, \beta = -0.11 \), and \( \Delta = 0.50 \). The fermi level \( E_F \) is set at zero.

Next, we study whether such perfect Andreev reflec-
tion is robust to perturbations of the electronic structure at the SC/TI interface. To this goal we consider the effect of onsite disorder, which is introduced by adding a term of the form $H_{\text{disorder}} = \sum_i w_i c_i^\dagger c_i$ to both $H_{\text{KM}}$ and $H_{\text{SH}}$. Here we choose the onsite energy, $w_i$, to be randomly distributed within the interval $[-W/2, W/2]$. Such disorder is introduced in a $n_x = 15$ site-long region near the SC/TI interface. From Fig. 3 it can be clearly seen that the Andreev reflection process is very robust against disorder. Even for moderately large disorder ($W \approx 2.0t$) $R^A$ remains perfectly quantized. This is attributed to the presence of the topological protected edge states, which are highly immune to impurities and disorder, and the situation is identical for both classes of topological insulators. For $W > 2.0t$ fluctuations in $R^A$ begin to develop in the energy range where only edge states exist. As a result the Fano factor becomes non-zero. This signals a transition from ballistic to diffusive transport where backscattering is allowed and the edge

Finally we introduce magnetic impurities at one of the TI ribbon edges. The exchange coupling between the electron spin and the impurities is incorporated into the model as [22]

$$H_{\text{ex}} = \sum_{i,\alpha,\beta} c_i^\dagger \left[ J_z \sigma_z^{\alpha\beta} S_i^\alpha + J_\parallel (\sigma_x^{\alpha\beta} S_i^x + \sigma_y^{\alpha\beta} S_i^y) \right] c_i^{\beta},$$

(6)

where $S_i^\alpha$ is $n$-th spin component of the magnetic impurity located at the edge site $i$, and $J_z$ and $J_\parallel$ are respectively the longitudinal and transverse exchange coupling. In the notation we have now explicitly re-introduced the spin index so that $c_i^\dagger_\alpha (c_i^{\alpha})$ is the creation (annihilation) operator for an electron at site $i$ with spin $\alpha$.

When one includes only the $z$-component of the exchange coupling in the Kane-Mele model, there is a shift of the up and down spin edge bands, by an amount proportional to the coupling $J_z$ but no band-gap opens in the edge state spectrum. For small values of $J_z$, before the bulk band-gap closes, the system is in the time-reversal symmetry broken Quantum Spin Hall phase predicted by Yang et al. [22]. As a consequence, although we have locally broken time-reversal symmetry, perfectly quantized Andreev reflection still occurs. This is because in the energy range within the superconducting gap there is only the counter-propagating opposite spin channel available to normal reflection.

In contrast, if we also include the transverse component of the exchange, i.e. we take $J_\parallel \neq 0$, then a gap is opened at the edge where the magnetic impurities have been located. The destruction of the helical edge states at one of the two edges leads to a suppression of this channel, which results in the Andreev reflection coefficient dropping from two to one, as shown in Fig. 4(a). Such a reduction of $R^A$ from 2 to 1 is almost perfect except for some bulk contributions at energies approximately equal to the superconducting gap. The situation for the spin-Haldane model is different and the magnetic impurities produce no effect, regardless of the magnitude of $J_z$ and $J_\parallel$. This is expected, since the topological protection of the edge states for a Chern insulator continues to hold even in the absence of time-reversal symmetry. Consequently, no such suppression is observed and the Andreev reflection coefficient remains perfectly quantized to a value of two, as illustrated in Fig. 4(b).

Thus, we have shown that Andreev reflection measurements can characterize a topological insulator and distinguish it from a topologically trivial material. Perfect Andreev reflection provides a signature for existence of topological edge states, although it is not unique to them. One can in fact envisage other systems, which display similar perfect electron hole conversion, for instance a pair of ballistic nanowires. What is unique, though, is the tremendous immunity to disorder, which both types of topological insulators display. Furthermore, we also showed that the $Z_2$ and Chern insulators respond differently to presence of magnetic impurities.

Based on this observation we propose a transport experiment to distinguish between the two types of topological insulators. The experiment involves placing magnetic impurities along one of the edges of the two-dimensional sample, for instance by using the tip of a Scanning Tunneling Microscope. The impurities’ spin will, in general, be aligned in arbitrary directions. The illumination with low-frequency polarized infrared light can however induce their alignment. This has been demonstrated, for instance, for Mn impurities in CdTe [24]. The infrared pulse imparts a momentum to align the impurity spins,
which subsequently relax back to their random orientations. The Andreev reflection coefficient $R^A$ can then be measured as a function of time, and this can be related to the inclination angle $\theta$ of the impurity spin $S$. The dependence of $R^A$ on $\theta$ is shown in Fig. 4. As the spin rotates towards the z-direction $R^A$ returns back to the perfectly quantized value of two, the same as that in absence of impurities. For Chern insulator the Andreev reflection process is unaffected by magnetic impurities and thus to the exposure with polarized light.

A second possible route to spin-polarize the impurities consists in applying an intense static magnetic field $B$ perpendicular to the plane of the sample, and then to switch it off over a short time scale $t_s$. The impurity spins will then relax back to their random configuration with a typical spin-relaxation time $t_S$. During the time window comprised between $t_L$ and $t_S$, measurements of $R^A$ should yield a behaviour similar to that shown in Fig. 5. We note that these possible approaches were already outlined in Ref. [11], relative to the observation of the Chern insulating phase in Mn doped HgTe quantum wells.

In conclusion, we have investigated SC/TI heterojunctions and shown that they display perfect Andreev reflection. The robustness of the topologically protected edge states lends this effect a large immunity against disorder. We have then looked at magnetic impurities and shown that in the case of transverse exchange coupling the Andreev reflection coefficient of $Z_2$ topological insulators drops from two to one. This observation allowed us to propose a transport experiment able to distinguish between the two types of topological insulators. This consists in following the time evolution of the Andreev reflection coefficient of a device dusted with magnetic impurities, which have been previously polarized.

We would like to thank Ivan Rungger for helpful suggestions. This work is sponsored by the Irish Research Council for Science, Engineering and Technology (IRCSET) under the EMBARK initiative. Computational resources have been provided by the Trinity Centre for High Performance Computing (TCHPC).
