Markedly increased intake of refined carbohydrates and sugar is associated with the rise of coronary heart disease and diabetes among the Alaskan Inuit

James J DiNicolantonio, James O’Keefe

In a recent issue of the journal, DiNicolantonio published evidence suggesting that an increase in the intake of refined carbohydrates and sugar paralleled the rise in the incidence of atherosclerotic disease in the Greenland Inuit. Thus, we sought to ascertain if a similar trend occurred in Alaskan Inuit by reviewing the literature as far back as the 1950s. Because of their relative isolation prior to the 1950s, studying the dietary changes that occurred in the Alaskan Inuit in the following decades can provide great insight into potential factors that may have caused a decline in their health.

The Inuit are said to be descendants of the Thule people who originally came to North America 3000 years ago from Asia through Siberia and the Bering Strait. The Inuit then travelled from Northwest Alaska towards Canada and Greenland and also south towards inland regions of Alaska. This paper will discuss Alaskan natives in general and Alaskan Inuit in particular.

In 1972, Dr Sheldon A Feldman, MD, and colleagues published a study on the Inuit living on Alaska’s North Slope (Point Hope). During the early 1970s, the Eskimos of Point Hope (known as the ‘Tigara’ people) were one of the few Inuit villages that still subsisted on whale and seal meat and blubber. Only two other villages at the time along Alaska’s North Slope continued the traditional hunting of whales using harpoons during the spring months. In the spring and early summer, these North Slope Alaskan Inuit mainly relied on catching and eating seal, walrus and fish. In the summer, the main dietary staple was caribou, and in winter, they would occasionally catch and eat polar bear. The consumption of grains and other carbohydrates was low due to the high cost of their import.

It has been estimated that the Alaskan Inuit consumed around 3000 calories per day, with 50% of their calories coming from fat, 30%–35% from protein and 15%–20% from carbohydrate. The estimated intake of carbohydrate (15%–20% of total calories) was largely estimated from glycogen stores in the meat however, and it was not known in 1972 that postmortem glycogen rapidly degrades to lactic acid. Thus, since most of the estimated carbohydrate intake was said to come from glycogen in the meat (which would have been degraded prior to consumption), the traditional Alaskan Inuit would have consumed less than 10% of their total calories as exogenous carbohydrate with virtually no consumption of refined sugar.

It has been estimated that the Alaskan Inuit consumed around 3000 calories per day, with 50% of their calories coming from fat, 30%–35% from protein and 15%–20% from carbohydrate. The estimated intake of carbohydrate (15%–20% of total calories) was largely estimated from glycogen stores in the meat however, and it was not known in 1972 that postmortem glycogen rapidly degrades to lactic acid. Thus, since most of the estimated carbohydrate intake was said to come from glycogen in the meat (which would have been degraded prior to consumption), the traditional Alaskan Inuit would have consumed less than 10% of their total calories as exogenous carbohydrate with virtually no consumption of refined sugar.

Indeed, the dietary pattern of the Alaskan Inuit was documented by Feldman in the following, ‘Grain products were scarce, and while sucrose was not unknown, the average adult ingested less than 30 grams a day of sucrose primarily as sweetening for tea or coffee’. Thus, the traditional Alaskan Inuit diet was very low in refined carbohydrates and sugar.

In 1972, Feldman and colleagues, based on previous observations and postmortem examinations from others, noted signs of atherosclerosis in the traditional Alaskan Inuit. However, there was little if any clinical manifestations of cardiovascular disease, ‘The Eskimos’ vasculature, indeed, showed some degree of atherosclerotic changes, but the severity was usually not enough to produce clinically recognizable symptoms and signs…Thus, atherosclerosis indeed exists in Eskimos, but is less severe and only rarely produces clinical manifestations and fatal complications. In contrast, in U.S. whites…they are suffering from a high incidence of atherosclerotic cardiovascular disease’.

In summary, clinical symptoms of atherosclerotic disease such as angina as well as clinical manifestations of heart disease were extremely rare in the traditional Alaskan Inuit.
Point Hope Inuit, which was in contrast to what was occurring in the USA at the time.2

**DYSLIPIDAEMIA**

With westernisation however came an increase in the intake of refined carbohydrates and sugar in the Alaskan Inuit. Indeed, compared with the Inuit of Point Hope, the Inuit living in a boarding high school consumed more carbohydrates (48% vs 10% of total calories), less fat (39% vs 55% of total calories) and less protein (14% vs 35% of total calories).2 This increase in the intake of carbohydrate appears to have contributed to dyslipidaemia in the Alaskan Inuit. Indeed, the average serum triglyceride level of the Point Hope Inuit was only 69 mg/dL. However, the triglyceride levels among boarding school Inuit were 124 mg/dL and 101 mg/dL, which represented increases of 80% and 46% in the men and women, respectively.2 Very low density lipoprotein (VLDL) levels of the Alaskan Inuit were also extremely low (<35 mg/dL) or about two to six times lower than levels found in US whites at the time (60–200 mg/dL).2

Feldman et al2 suggested that the increase in the triglyceride levels in the boarding school Inuit was likely due to ‘A diet rich in carbohydrates, particularly simple sugars, which elevates serum triglyceride levels due to the increased availability of triglyceride precursors such as acetyl CoA and glycerol-6-phosphate which favors a net synthesis of triglycerides. The reverse conditions were true for Point Hope Eskimos. Their lipogenesis must be inhibited by the relative scarcity of these precursors due to a low carbohydrate intake. Moreover, it would be expected that Point Hope Eskimos would have low insulin values...’ In other words, the high carbohydrate diet and subsequent higher insulin levels were thought to be likely drivers of higher triglyceride levels in Alaskan Inuit consuming a more Western diet.

**CARDIOVASCULAR DISEASE**

Gottman discovered the true incidence of cardiovascular disease in Alaskan natives by performing a large post-mortem study between 1956 and 1958. He found that death due to acquired cardiovascular disease at autopsy was just 5.8%.2,3 Another large autopsy study conducted during the same time period (1955–1959) in the USA found that 30.6% of all deaths were due to morphological evidence of atherosclerotic catastrophe in the heart, aorta or brain.4 In other words, the Alaskan Inuit apparently had a fivefold lower cardiovascular mortality rate versus those in the USA at the time. Another autopsy study, this time spanning the subsequent decade (ie, 1959–1968), found a prevalence of cardiovascular disease of only 10.3% in Alaskan natives.2 Thus, even during the 1960s, Alaskan natives had a threefold lower incidence of death due to cardiovascular disease compared with that of the USA.

The incidence of ischaemic heart disease based on autopsy studies was just 1% in Alaskan Inuit (1956–1958)2,3 versus 18.44% (1950–1955)4 in the USA and just 2% in Alaskan Inuit (1959–1968) but 30% in the USA (1964).5–7 Thus, the data suggest that the traditional Alaskan Inuit (based on autopsy studies from the 1950s and 1960s) had around 1/15th to 1/18th the rate of death from ischaemic heart disease compared with the USA at the time.

The Alaskan Inuit also had a much milder form of atherosclerosis compared with that found in the Western world. Feldman et al2 noted, ‘These postmortem studies, however, also disclosed the fact that about 10% of the Eskimo population did have a significant degree of atherosclerosis. Roentgenological (x-ray) evidence of atherosclerosis of the aortic arch was detected by Rodahl in three out of nine Eskimos over 47 years of age (33%). Therefore, the Eskimos did develop atherosclerosis which was mild in degree, of limited clinical significance, and certainly did not account for one of the major causes of death among them’.

It is sometimes argued that because Eskimos usually die younger than those in the Western world (due to infections, accidents or harsh weather), this may skew the results in favour of the Eskimos. However, comparing the incidence of atherosclerosis in Alaskan Inuit who are over 47 years old (33%) with data from the International Atherosclerosis Project (1960–1965), an autopsy study of men encompassing 23,207 sets of coronary arteries and aorta from 14 countries found an incidence of atherosclerosis of 71%–82% in blacks/Caucasians aged 45–54 years old living in New Orleans.4 Cases with fibrous atherosclerotic plaques for all 14 countries studied were 58%–96%.

In summary, based on X-ray exams, older Alaskan natives had about one-half to one-third the rate of atherosclerosis compared with 14 other more westernised populations on autopsies. Autopsy studies in the mid-to-late 1950s in Alaskan Inuit showed around one-fifth the rate of death from cardiovascular disease (5.8%) as compared with those in the USA (30.6%) during the same time period, and based on autopsy studies, the rate of death from ischaemic heart disease in Alaskan Inuit was around 1/18th that of the USA (1% vs 18.44%).2 Future studies with a more robust design may be needed to more accurately confirm these findings.

The more current data in Alaska (1979–2002) looks more dismal compared with these earlier data. Based on death certificate data, ‘Alaska Natives were previously at a lower risk for death from CHD than were non-native Alaskans; however, this discrepancy has disappeared. Alaska Natives currently have a higher prevalence of numerous risk factors for coronary heart disease compared with non-native Alaskans’.9,10 Indeed, in the late 1970s, death due to heart disease in Alaskan natives was only about 20% lower versus US whites, and by the mid-1980s, the rates were nearly identical.10 Thus, Alaskan natives who had previously had
Table 1 The health of populations consuming a Western diet versus a traditional Alaskan native

| Health marker                  | Point Hope Inuit (Traditional Eskimo diet) | Boarding school Inuit (Western diet) |
|--------------------------------|-------------------------------------------|-------------------------------------|
| Caloric intake                | 3000 calories                              | 2000 calories                       |
| Carbohydrate intake (Sugar intake) | ≤10%<30 g/day                              | ~47%                               |
|                               | ‘Grain products were scarce, and while sucrose was not unknown, the average adult ingested less than 30 grams a day of sucrose (around 7 teaspoonful or less per day of sugar), primarily as sweetening for tea or coffee’.2* | A diet rich in carbohydrates, particularly simple sugars.2* |
| Fat intake                    | ~55%                                      | ~39%                               |
| Protein intake                | ~35%                                      | ~14%                               |
| Triglyceride level            | 69 mg/dL                                  | 124 mg/dL (men)                    |
|                               |                                           | 101 mg/dL (women)                  |
| VLDL                          | <35 mg/dL                                 | 60–200 mg/dL                       |
|                               | Traditional Alaskan Inuit                 | Westernised populations            |
| Ischaemic heart disease (IHD) | 5/1000 people (based on physical examination, chest X-ray films and electrocardiography among 779 North Slope Inuit) | 50/1000 people (~1970, general US population per Feldman et al) |
| Atherosclerosis                | 33%2 (mild atherosclerosis) Description: Natives >47 years, X-ray evidence in 1954 publication ‘Roentgenological (x-ray) evidence of atherosclerosis of the aortic arch was detected by Rodahl in three out of nine Eskimos over 47 years of age (33%). Therefore, the Eskimos did develop atherosclerosis which was mild in degree, of limited clinical significance, and certainly did not account for one of the major causes of death among them’.2 77%–82%8 (cases with fibrous atherosclerotic plaques) 58%–96% (cases with fibrous atherosclerotic plaques, all 14 countries studied) Description: 71%–82% is from New Orleans (blacks/Caucasians, respectively), in 45–54 years old, 1960–1965. These data are from the International Atherosclerosis Project – 1960–1965 autopsy study of 23 207 sets of coronary arteries and aorta from 14 countries (table 1) in men who died of accidents, cancer, infection and miscellaneous causes 77.3%19 (Atherosclerotic coronary involvement) Young Korean War vets, 1953 autopsy study The approximate 30-year age gap between these young Korean War veterans and the older native Alaskans helps to control for the high rates of smoking in these young vets and the stress of being at war. |
| IHD mortality                  | ~1%2 (1956–1958 – myocardial infarction, aortic aneurysm and generalised atherosclerosis on autopsy) | 18.44%5 (Deaths due to IHD – autopsy study in the USA between 1950–1955) |
|                               | ~2%2 (1959–1968 – myocardial infarction, aortic aneurysm and generalised atherosclerosis on autopsy) | 30%1 (USA 1964 – arteriosclerotic heart disease including coronary disease mortality) |
| Deaths due to acquired cardiovascular disease (Eskimo) | 5.8%23 (Deaths due to acquired cardiovascular disease, Gottman autopsy study of Alaskan natives between 1956 and 1958, n=60 of 103) 10.3%23 (Deaths due to acquired cardiovascular disease, Arthaud autopsy study of Alaskan natives between 1959 and 1968, n=35/339) | 30.6%4 (Deaths from morphological evidence of atherosclerotic catastrophe in the heart, aorta or brain – 1955–1959) |
| Diabetes                       | More westernised Alaskan Inuit             | With acculturation, there was a tripling in the prevalence of type 2 diabetes.18 |

*Feldman’s explanation as to why the boarding school Eskimos had elevated TG levels. VLDL, very low density lipoprotein.
just 1/18th the rate of death due to ischaemic heart disease in the mid-1950s had an identical rate of heart disease mortality by the mid-1980s compared with the USA. Importantly, one of the major dietary changes that occurred in the mid-1950s in Alaskan Inuit was an increase in the intake of carbohydrates and simple sugars.11

DIABETES
In the 1950s, only five diagnoses of diabetes had been made from eight hospitals serving Alaskan Inuit, ‘Five hospitals had never seen diabetes mellitus in an Eskimo’.12 More importantly, ‘Vital statistics reports showed 35 deaths due to diabetes in Alaska in the years 1919–1951, but none of these were in Eskimos’.12 In other words, prior to 1950, diabetes was virtually non-existent in the Alaskan Inuit. Scott and Griffith in 1957 wrote, ‘Diabetes mellitus was not detected in the 869 Eskimo National Guardsmen tested’.12 Thus, diabetes was apparently absent in Alaskan Inuit even up to 1957. Interestingly, the intake of carbohydrates among Alaskan Inuit increased by around 50% from 1957 to 1965,13 and by the early 1970s, the rate of diabetes in Alaskan natives had tripled.13 This suggests that the increase in the intake of refined carbohydrates in the Alaskan Inuit may have contributed to their rise in diabetes. These dietary changes and the associated negative health consequences are summarised in table 1.

CONCLUSION
The traditional Alaskan Inuit diet consisted of less 10% of total calories as carbohydrate. Even with the introduction of sugar, early on, the total intake would have been less than 5% of total calories. Nowadays, however, sugar-sweetened beverages are the main sources of calories in Alaskan natives14 with added sugars making up 20% of the total caloric intake compared with 14% of calories consumed in general US population.15 16 Importantly, a higher intake of low-nutrient-dense carbohydrates is associated with a higher rate of type 2 diabetes in Alaskan natives.17 The evidence suggests that an increase in the intake of refined carbohydrates and sugar may have contributed to the health decline of the Alaskan Inuit. Thus, a reduction in the intake of refined carbohydrates and sugar may drastically improve the health of Alaskan natives.
