Development of Jaw and Deciduous Teeth in Japanese Children
—Comparing Size of Crown and Alveolar Area between Today and 40 Years Ago—

Abstract

The purpose of the present study was to investigate change in the size of the jaw and deciduous teeth in Japanese children over the past 40 years by performing measurements on plaster models of the dental arch obtained from children born between 2007 and 2009 (2000s group) and children born between 1968 and 1974 (70s group). A total of 61 children were enrolled in the 2000s group, comprising 25 boys (average age, 4 years 5 months) and 36 girls (average age, 4 years 4 months), and 93 children in the 70s group, comprising 45 boys (4 years 6 months) and 48 girls (4 years 4 months). The mesiodistal width of the crown, dental arch width, dental arch length, dental arch height, and available arch length in these groups were measured using a 3D measurement system and the sums of the mesiodistal width of the crown and tooth size-arch length discrepancies calculated. The results of the two groups were statistically compared and the following conclusions reached: the size of deciduous teeth has not changed statistically over the last 40 years; the size of the dental arch has decreased in boys (p<0.01), while remaining approximately the same in girls; and the tooth size-arch length discrepancy has decreased, especially in boys (p<0.01). These results indicate that the interdental spaces of the deciduous dentition have decreased, increasing the risk of crowding in Japanese children.

Key words: Infants — Deciduous dentition — Deciduous teeth — Development — Growth

This paper was a thesis submitted to the Graduate School of Tokyo Dental College by Dr. T. Makiguchi.
Introduction

Conservation of the primitive morphology means that little change occurs in the crown of deciduous teeth compared with that in the permanent teeth\(^5,7\). Similarly, little change is observed in the morphology of the deciduous dental arch compared with the permanent dentition, as the former is barely influenced by environmental factors\(^5,10,13\). On the other hand, in the case of children, rapid environmental change, such as in diet, impacts both physical and psychological development, including in the oral and dental organs\(^9,14\).

One earlier study compared plaster models of the deciduous dentition obtained from Caucasians between now and 50 years ago. The results revealed that the mesiodistal width of the crown was either the same or slightly larger, and that the discrepancy in tooth size-arch length decreased in both sexes. They also showed a marked increase in crowding in the mandibular deciduous dentition\(^15\).

Some studies have reported differences in the dentition between past and present in Japanese populations\(^1–3,8\). Few studies have compared differences in the sizes of the deciduous teeth and dental arch between past and present in such a population, however.

The purpose of the present study was to investigate change in the size of the deciduous teeth and dental arch and tooth size-arch length discrepancies in Japanese children over the last 40 years.

Materials and Methods

1. Study materials

   1) Group born between 1968 and 1974

   A total of 93 dental arch plaster models were obtained from 45 boys and 48 girls who had normal occlusion on impression-taking at the age of 4 years and 6 months (boys), at the age of 4 years and 4 months (girls). All these children were born between 1968 and 1974 (hereafter, 70s group). Sampling was performed with the agreement of the child and guardian. Any damage, caries, or restoration that might have skewed the measurements meant exclusion from the study.

   2) Group born between 2007 and 2009

   A total of 61 dental arch plaster models were obtained from children born between 2007 and 2009 (hereafter, 2000s group), comprising 25 from boys (average age, 4 years 5 months) and 36 from girls (average age, 4 years 4 months) with normal occlusion. Sampling was performed with the agreement of the child and guardian. Any damage, caries, or restoration that might have skewed the measurements meant exclusion from the study.

   The present study was approved by the Ethics Review Board of Tokyo Dental College (Approval number: 295).

2. Methods

   1) Measurement methods

   All the dental arch models were measured using a 3D measurement system (DORA\(^\circ\) by 3D! Co., Ltd., Tokyo, Japan). All the models were imported to a computer by a trained engineer and measurement performed using this system which allows measurement to an accuracy of within 10 to 30 \(\mu\)m. Undercut and areas difficult to measure were enlarged or sectioned using CAD to ensure accuracy.

   2) Measurement sites

   The mesiodistal width of all the deciduous teeth crowns was measured and the sums were calculated. The average value for each tooth type in each model was calculated to determine mesiodistal crown width. To determine dental arch size, measurement was performed based on the standards recommended by the Japanese Society of Pediatric Dentistry in 1993 (Fig. 1)\(^10\). Dental arch width (6 measurement points in each jaw), dental arch length (3 measurement points in each jaw), and dental arch height (2 measurement points) were determined. The measurement sites and reference points were as follows:

   a: the distance between the maxillary and mandibular bilateral canine cusps (\(C_L-C_R\));

   b: the distance between the lowest points in the cervical area of the palatal (lingual) side
of the maxillary and mandibular deciduous canines (C<sub>1</sub>-C<sub>1</sub>);

c: the distance between the buccal cusps of the maxillary bilateral first deciduous molars (D-D), and that between the buccal terminal sulci of the mandibular bilateral first deciduous molars (D-D);

d: the distance between the lowest points in the cervical area of the palatal side of the maxillary bilateral first deciduous molars (D<sub>L</sub>-D<sub>L</sub>), and that between the sub-lingual sulci of the lingual mesiodistal cusps of the mandibular bilateral first deciduous molars (D<sub>L</sub>-D<sub>L</sub>);

e: the distance between the buccal terminal sulci of the maxillary bilateral second deciduous molars (E-E), and that between the mesial buccal terminal sulci of the mandibular bilateral second deciduous molars (E-E); and

f: the distance between the lowest points in the cervical area of the palatal (lingual) side of the maxillary and mandibular bilateral second deciduous molars (E<sub>L</sub>-E<sub>L</sub>).

(2) Dental arch length

g: the length of the perpendicular line from the center of the line connecting the labial surface of the bilateral deciduous central incisors to the bilateral deciduous canine cusps (A-C<sub>c</sub>);

h: the length of the perpendicular line from the center of the line connecting the labial surface of the bilateral deciduous central incisors to the mesial buccal terminal sulci of the bilateral second deciduous molars (A-E);

i: the length of the perpendicular line from the center of the line connecting the labial surface of the bilateral deciduous central incisors to the most distal edges of the bilateral second deciduous molars (A-E<sub>D</sub>);

(3) Dental arch height

j: the distance between the interdental papillae of the maxillary and mandibular bilateral deciduous central incisors (dental height); and

k: the distance between the center of the cervical area of the labial surface of the maxillary and mandibular left deciduous central incisors (ULA-LLA).

Available arch length was calculated by adding A, B, C, and D (Fig. 2). Measurements in both the maxilla and mandible were made in accordance with the criteria below, which were reported in an earlier study<sup>15</sup>:

A and C: the distance between the most
mesial point of the deciduous central incisor and the most distal point of the deciduous canine.

B and D: the distance between the most distal point of the deciduous canine and the most distal point of the deciduous second molar.

When there is a space between the central incisors, the most mesial point of the left deciduous central incisor is used as the reference.

Tooth size-arch length discrepancy (TSALD) is calculated by subtracting the sums of the mesiodistal width of the crown from the available arch length.

3) Statistical processing

An unpaired t-test was used to establish differences in the mean values between the two groups. Statistical analysis was performed using SPSS version 11.0 software (IBM, Tokyo, Japan). This was done for the mesiodistal width of the crown; the sums of the mesiodistal width of the crown; dental arch width; dental arch length; dental arch height; available arch length; and TSALD. A p value of <0.01 or <0.05 was considered to indicate significance.

An age difference has been reported in available arch length. The number of cases required was determined by a two-sided test on 5 preliminary cases at a significance level of 0.05 and 80% power. The difference in the average value for the maxillary deciduous dental arch in boys between the two groups was 2.1 mm, with an estimated standard deviation of 1.9. Therefore, the number of cases required was estimated to be more than 13. Similarly, the difference in the average value for the mandibular deciduous dental arch in boys between the two groups was estimated to be 2.4 mm, with an estimated standard deviation of 3.2. Therefore, the number of cases necessary was estimated to be more than 28.

Results

1. Mesiodistal width of deciduous crown

1) Difference in each tooth type between groups (Table 1)

For boys, the mesiodistal crown width of the maxillary deciduous central incisor (p<0.01), mandibular deciduous central incisor (p<0.05), and mandibular deciduous lateral incisor (p<0.01) was significantly larger in the 2000s group. Conversely, the mesiodistal crown width of the maxillary deciduous second molar (p<0.01) was significantly larger in the 70s group. No significant difference was observed in the other tooth types.

For girls, the mesiodistal crown width of the

SD: Standard deviation. **p<0.01  *p<0.05
maxillary deciduous canine \((p<0.01)\) was significantly larger in the 2000s group, and that of the maxillary deciduous second molar \((p<0.01)\) was significantly larger in the 70s group. No significant difference was observed in the other tooth types.

2) Differences in sums between groups (Table 2)

No significant difference was observed in the sums of the mesiodistal crown width in either sex or jaw between the 70s and 2000s groups.

2. Dental arch size

1) Differences in dental arch width, length, and height between groups (Table 3)

(1) Dental arch width

As regards dental arch width in boys, the mandibular D-D was significantly greater in the 2000s group \((p<0.01)\), whereas the other measurements were slightly larger in the 70s group or approximately the same. As regards dental arch width in girls, no significant difference was observed in the maxilla, but it was either slightly larger or approximately the same in the 2000s group (Fig. 3). The mandibular D-D was significantly greater in the 2000s group \((p<0.01)\), whereas \(E_6-E_7\) was significantly greater in the 70s group \((p<0.05)\). Other measurements were slightly larger in the 70s group or approximately the same (Fig. 3).

(2) Dental arch length

As regards dental arch length in boys, the maxillary A-C was significantly greater in the 2000s group \((p<0.05)\), whereas the maxillary A-E was significantly greater in the 70s group \((p<0.05)\). No significant difference was observed in the other dental arch length measurements. No significant difference was observed in dental arch length measurements in girls between the 70s and 2000s groups (Fig. 4).

(3) Dental arch height

As regards dental arch height in boys, both measurements were significantly larger in the 2000s group \((p<0.01)\). Although no significant difference was observed in girls, both measurements were slightly larger in the
2000s group (Fig. 5).

2) Differences in available arch length between groups (Table 4)

The available arch length in boys was significantly greater in the 70s group for both the maxilla and mandible (p < 0.01). No significant difference was observed in girls between the 70s and 2000s groups.

3. Differences in tooth size-arch length discrepancy between groups

As can be seen in Table 5, TSALD in boys was significantly greater in the 70s group for both the maxilla and mandible (p < 0.01). No significant difference was observed in TSALD in girls between the 70s and 2000s groups.

Table 4  Age difference in deciduous available dental arch length

| Sex   | Jaw   | 70s group | 2000s group | Age difference |
|-------|-------|-----------|-------------|----------------|
|       |       | Mean ± SD (mm) | Mean ± SD (mm) |                  |
| Boys  | Maxilla | 74.1 ± 3.1 | 71.9 ± 2.1 | **              |
|       | Mandible | 68.6 ± 2.9 | 66.7 ± 1.5 | **              |
| Girls | Maxilla | 72.0 ± 2.7 | 71.2 ± 2.6 |                |
|       | Mandible | 66.7 ± 2.5 | 66.1 ± 2.6 |                |

SD: Standard deviation. **p<0.01

Table 5  Age difference in tooth size-arch length discrepancy

| Sex   | Jaw   | 70s group | 2000s group | Age difference |
|-------|-------|-----------|-------------|----------------|
|       |       | Mean ± SD (mm) | Mean ± SD (mm) |                  |
| Boys  | Maxilla | 2.8 ± 2.7 | 0.5 ± 2.8 | **              |
|       | Mandible | 1.8 ± 2.6 | −0.4 ± 2.2 | **              |
| Girls | Maxilla | 2.0 ± 2.5 | 1.1 ± 2.7 |                |
|       | Mandible | 0.9 ± 2.4 | −0.0 ± 1.8 |                |

SD: Standard deviation. **p<0.01

Discussion

1. Measurement method

The 3D measurement system used in the present study allows readings to be made with an accuracy of within 10 to 30 μm. Undercut and areas difficult to measure were enlarged or sectioned using CAD to ensure accuracy. We believe that this system offered sufficient accuracy of measurement for the present purposes based on earlier studies, including one that measured dental plaster models to evaluate its accuracy and found it to be as good as that obtainable with a caliper[^11].

2. Mesiodistal width of deciduous crown

1) Differences by tooth type between groups

As regards differences in mesiodistal width of the deciduous crown in boys, only the maxillary second molar was significantly greater in the 70s group, while the maxillary and man-
dibular deciduous central incisors and mandibular deciduous lateral incisor were significantly wider in the 2000s group. No major difference was observed overall. In a study carried out in 2002 comparing mesiodistal width of the deciduous crown with that in a population 20 years earlier, little difference was observed in boys. In the present study, however, 3 incisors were significantly larger and the maxillary second molar significantly smaller in the 2000s group. This suggests that the deciduous frontal teeth have become slightly larger and deciduous molars slightly smaller over the past 40 years.

In one earlier study, the sums of the mesiodistal widths of the mandibular deciduous crowns showed a significant increase in girls. In another study, the maxillary deciduous central incisors and mandibular deciduous lateral incisors and canines showed a significant increase in the mesiodistal width of the deciduous crown over the past 20 years in girls. All the other tooth types also showed an increase in mesiodistal width of the deciduous crown over the past 20 years, although the difference was not significant. The results of the present study showed a significant increase in the maxillary deciduous canine and significant decrease in the maxillary deciduous second molar in girls. Although not as marked as in boys, the deciduous frontal teeth in girls showed a slight increase in size, whereas the deciduous molars showed a slight decrease or remained approximately the same. Taken together, this suggests that differences in the mesiodistal width of the deciduous crown were smaller in girls than in boys.

The maxillary deciduous second molars were smaller in the 2000s group than in the 70s group in both sexes. This suggests that the mesiodistal width of the deciduous maxillary second molars in Japanese children has decreased. This further suggests a relative decrease in the maxillary leeway space. We believe that these changes in the mesiodistal width of the deciduous crown have affected the deciduous dental arch and occlusion in Japanese children.

2) Difference in sums between groups

No significant difference was observed in the sums of the mesiodistal width of the maxillary and mandibular deciduous crowns in either sex between the 70s and 2000s groups. This finding agrees with that of an earlier study comparing the sums of the mesiodistal width of 50 years ago using deciduous dental arch plaster models obtained from Caucasians. They found that the sums of the mesiodistal width of the mandibular deciduous crowns showed a significant increase in girls, but no other significant difference. They reported that the mesiodistal width of the deciduous crown had shown a slight increase or remained approximately the same over the past 50 years. Similarly, in the present study, the sums of the mesiodistal width of the deciduous crown showed little change over the past 40 years in a Japanese population. Considering the previously-described size comparison by tooth type, this suggests that little change has occurred in the sums of the mesiodistal width of the Japanese deciduous crown over the past 40 years.

3. Dental arch size

1) Difference in dental arch width between groups

A comparison of deciduous dental arch width between the 70s and 2000s groups revealed a significant increase in the mandibular D-D only in the 2000s group in boys, whereas all the other measurements were greater in the 70s group, although the difference was not significant. This suggests that the deciduous dental arch width has become slightly smaller or remained approximately the same over the past 40 years.

The results in girls showed a different trend between the maxilla and mandible. While there was little change in maxillary C_l-C_r, all the other measurements were greater in the 2000s group, although the difference was not significant. In the mandible, however, D-D was significantly greater in the 2000s group, while all the other measurements were greater in the 70s group, including E_l-E_r, which showed a significant difference.

In the maxilla, deciduous dental arch width
in girls has shown a slight increase or remained approximately the same over the past 40 years, while in the mandible in boys it has shown a slight decrease or remained approximately the same. One earlier study also reported that crowding during the deciduous dentition period showed an increase\textsuperscript{15}. In the present study, although $C_l-C_n$ and $C_r-C_c$ remained approximately the same in the 2000s group compared with in the 70s group in both sexes, the mesiodistal width of the deciduous frontal teeth, including the canines, showed a tendency to be significantly larger in the 2000s group. We believe that this may cause crowding.

2) Difference in dental arch length between groups

A comparison of deciduous dental arch length between the 70s and 2000s groups revealed an increase in 2 (one of them showed a significant difference) of the 6 measurement points in the 2000s group in boys, and an increase in the other 4 measurement points (one of them showed a significant difference) in the 70s group. This suggests that deciduous dental arch length has become slightly smaller or remained approximately the same in boys over the past 40 years. Although there was no significant difference, 5 of the 6 measurement points showed an increase in the 70s group in girls. This suggests that the deciduous dental arch length has become slightly smaller or remained approximately the same in girls.

3) Difference in dental arch height between groups

A comparison of deciduous dental arch height between the 70s and 2000s groups revealed significantly larger values in boys in the 2000s group. This suggests that deciduous dental arch height has increased over the past 40 years. We believe that dental attrition may have affected this result due to changes in the soft diet over the past 40 years.

4) Difference in available arch length between groups

Available arch length showed a significant decrease in both the maxilla and mandible in the 2000s group in boys while remaining approximately the same in girls. Considering the previously-described results for dental arch width and length, this suggests that the size of the deciduous dental arch has decreased in boys over the past 40 years. The available arch length was significantly larger in boys ($p<0.01$) in both the maxilla and mandible in the 70s group, but there was no significant difference in the 2000s group. This suggests that the deciduous dental arch has become significantly smaller in boys while remaining approximately the same in girls over the past 40 years in this Japanese population, leading to a decrease in the difference between sexes.

4. Difference in tooth size-arch length discrepancy between groups

The TSALD was significantly greater in both the maxilla and mandible in the 70s group in boys and greater in the 70s group in girls. These results were similar to those of an earlier study\textsuperscript{15}. This suggests that the interdental space in Japanese deciduous dentition has decreased over the past 40 years, especially in boys. We believe that these results are related to the decrease in deciduous dental arch size. A closed dental arch with little interdental space during the deciduous dentition period results in a higher rate of crowding in the permanent dentition\textsuperscript{15}. The results of the present study suggest that the risk of crowding has increased in the mandible in Japanese children, especially in boys.
