ABSTRACT

Background: The worldwide prevalence of obesity is increasing. Obesity is associated with many factors, including the consumption pattern of energy-producing food, i.e. carbohydrate and fat, which is, most likely associated with ethnicity. In Riskesdas 2007, Jayapura held the highest prevalence of obesity in adults in Indonesia. Jayapura lived the Papuan and Non-Papuan descents population. Objective: To determine the association between energy intake, the contribution of carbohydrate and fat to energy intake in overweight/obesity in Papuan and non-Papuan high-school students. Methods: This cross-sectional study involved 150 Papuan and 150 non-Papuan students from three high schools in the district. Body mass index (BMI) derived from the measurement of body weight and height were grouped into overweight/obesity and not-overweight/obesity. Source of energy was estimated using 3 (three) days non-consecutive 24 hours of food recall questionnaire. Energy intake and the contribution of carbohydrate and fat to energy intake were analyzed with an independent t-test and Chi-Square test. Results: The prevalence of overweight/obesity was similar between Papuan and non-Papuan students (22.0 vs. 23.0%). The two groups had a similar amount of energy intake, however, the contribution of carbohydrate and fat to the total energy intake was significantly different. Obese/overweight students had a significantly higher intake of energy, however, within the same ethnic group, the contribution of carbohydrate and fat in obese/overweight students did not significantly differ. Conclusions: High energy intake was associated with overweight/obesity in both groups. The contribution of carbohydrates to total energy intake was higher in Papuan. However, the contribution of carbohydrate and fat to energy intake was not associated with overweight/obesity in both groups.

KEYWORDS: contribution of carbohydrate; contribution of fat; energy intake; obesity; overweight; Papuan

INTRODUCTION

Obesity has become a worldwide health problem. The World Health Organization (WHO) estimated an increase of 2.8 million deaths correlated to overweight and obesity in the last 5 years (1). Overweight and obesity in children and adolescents is especially important, because early overweight/obesity may lead to more serious consequences in adulthood (2,3).

Riskesdas 2007 showed the prevalence of overweight/obesity in adult in Indonesia (age >15 years) were 23.5%. Jayapura had the highest prevalence, i.e. 35.9%, and was increasing (4-6). As Papuan had different ethnicity compared to the rest of Indonesia, it is interesting to learn why they had higher prevalence of overweight/obesity.

Overweight/obesity was known to be related to multiple factors, among others, energy intake, activity pattern, and also, probably, genetic susceptibility (7). There had been many controversies about the role of certain nutrients for obesity. Carbohydrate had been always regarded as nutrients that caused obesity (8,9). As food consumption pattern were more likely associated with ethnicity, the objective of this study was to determine
the association between energy intake, contribution of carbohydrate and fat to energy intake in overweight/obesity in Papuan and non-Papuan high-school students.

METHODS
Study design and participants
This cross-sectional study involved 15-18 years old Papuan and non-Papuan adolescents from the three high schools in the district of Abepura, Jayapura. The students were grouped into Papuan when both their parents were purely of Papuan descents, and Non-Papuan when both their parents were not Papuan.

The calculated minimal sample size, with a confidence interval of $Z_{\alpha}=95\%$, were 146 for each group. The study invited 150 Papuan and 150 non-Papuan high school students who met the inclusion and exclusion criteria. The inclusion criteria were either Papuan or non-Papuan, born in Papua or living in Papua since childhood and within 15-18 years old. The exclusion criteria were being underweight, following a special diet, and having physical features which may influence anthropometric measures. Ethical approval were obtained from the Medical and Health Research Ethics Committee, Faculty of Medicine, Universitas Gadjah Mada/ Dr. Sardjito Hospital. Informed consents were signed by parents.

Measures
Body mass index (BMI). All participants underwent anthropometric assessments: weights were measured using a calibrated weighing scale to the nearest 0.1 kg (Camry EB9003), heights were measured using a microtois (GEA SH-2A), in a standardized methods. All enumerators, who were D3 students in nutrition, were already trained for anthropometric measurements. Data collection were directly supervised by the principle investigator. BMI were calculated as height (in meter) divided by squared weight (in kg). The BMI were then grouped into overweight/obese and not overweight/obese using WHO 2007 reference curve, i.e. $Z \leq +1SD$: not overweight; $Z >+1SD$: overweight/obese.

Source of energy intake. Energy intakes and their sources (carbohydrate or fat) were estimated using 3 (three) 24 hours food recalls: 2 (two) working days and 1 (one) weekend. The data were converted into grams and kilocalories (kcal) using Nutrisurvey 2007, on which the nutrient contents of local food had been already added. Average of the three recalls were used in the final analyses. Energy intakes in kcal were compared to the recommended dietary allowance (RDA) for age and gender. The results were grouped into: high (>100%), sufficient (70-100%), and low (<70%) of the RDA.

Data analysis
Comparison of continuous variables were performed with independent samples t-test. Statistical analysis for dichotomous variables were performed with Chi-Square. We estimated the odds ratio (OR) and their 95% confidence interval (95%CI) for overweight/obesity related to feeding pattern and ethnicity group. We also calculated Mentel Haenszel OR between the Papuan and the non-Papuan group in relation with their feeding pattern. Statistically significant value were set at $p<0.005$.

RESULTS
The prevalence of overweight/obesity were 22% in Papuan adolescents and 23.3% in the non-Papuan. The difference was not statistically significant. Table 1 showed that the non-Papuan students were younger, were more likely to have more educated parents who were more likely to work in the formal sectors.

Table 2 showed that there was no difference in energy intakes between both ethnicity, however, the Papuan had significantly higher intake of carbohydrate and less fat. Table 3 showed that there was no significant difference in the proportion of adolescents who consume high, sufficient or low energy intake, however, the source of the energy was significantly different. Most of the Papuans had most of their energy intake from carbohydrate, while the non-Papuans eat more fat.

Table 4 showed comparison of energy intake and contribution of carbohydrate and fat to energy intake by nutritional status and ethnic group. The table showed that both in Papuan and non-Papuan, overweight and obese adolescents consume more energy from carbohydrate and fat. However, the difference in the contribution of carbohydrate and fat to energy intake were more related
**Tabel 1. The characteristics of the respondents**

| Characteristics                        | Papuan (n=150) | non-Papuan (n=150) | p  |
|-----------------------------------------|----------------|-------------------|----|
| **Age (years)**                         |                |                   |    |
| 15 – 16                                 | 95             | 117               | 0.005 |
| 17 – 18                                 | 55             | 33                |    |

RDA = recommended dietary allowance

to the ethnicity instead of the nutritional status because this table showed that the contribution of carbohydrate and fat to energy intake between the overweight/obese group vs. the non-overweight/obese group within the ethnicity were not significantly different. Similar conclusions were observed from Table 5.

**DISCUSSION**

Our study showed that the prevalence of overweight/obesity were similar between Papuan and non-Papuan students (22.0 vs. 23.0%). The two groups had similar amount of energy intake, however, the contribution of carbohydrate and fat to the total energy intake were...
significantly different. The Papuan had significantly higher contribution of carbohydrate to the total energy. This study had observed that obese/overweight students had significantly higher intake of energy, however, within the same ethnic group, the contribution of carbohydrate and fat in obese/overweight students did not significantly differ.

Overweight/obesity was the result of high total energy intake and low energy output. It was also called positive energy equilibrium (10). This was seen in the Papuan and non-Papuan overweight/obesity group. High total energy intake was associated with overweight/obesity in both groups. Similar association were observed in other studies. Adolescents with higher total energy intake had a 6.9 times higher risk of overweight and obesity (11,12).

Ethnic background was found as modifiable factor of energy intake and was related to overweight/obesity. Papuan with a high energy intake had a 15.52 chance of overweight/obesity, while non-Papuan had a 6.4 chance of overweight/obesity. As risk for overweight/obesity might be associated not only with food consumption pattern or energy intake, other risk factors differences of both groups, such as, probably activity pattern or genetic pattern, might be the explaining
factor for the difference in risks. The possibility to be overweight was higher in Papuan than non-Papuan. Generally obesity is correlated to inequilibrium of energy in the body, genetics and biologic factors. So that subjects with a balanced energy take have a smaller possibility to experience overweight/obesity (7).

Carbohydrate is the main energy source for our body and contributes to the total surplus of energy hence increasing bodyweight (7). Independent sample t-tests exposed that energy from carbohydrates intake in Papuan were higher than non-Papuan. This shows that carbohydrate rich foods were mainly consumed by Papuan.

The result of the bivariable analysis did not show any correlation between carbohydrate energy contribution. Even though there was no correlation, from the recall 24 hours in 3 days in a row it was found that both groups had a high sugar intake. In average both study groups ingested ±10-30 grams sugar per meal.

Previous researches showed that the decrease of simple carbohydrates in form of liquid sugars was more effective in weight reduction than other ways to reduce intake. Limitation of soft drinks could decrease the obesity on children (13,14).

The insignificant result in this research could be caused by not what kinds of carbohydrate by the participants. BMI was positively correlated to glicemic index of specific carbohydrates and was not related to the amount or percentage of carbohydrate intake (15). In another studies a negative correlation was found between carbohydrate and protein energy contribution and total energy intake (16).

CONCLUSIONS

High energy intake was associated with overweight/obesity in both groups. Contribution of carbohydrate to total energy intake was higher in Papuan. However, the
contribution of carbohydrate and fat to energy intake were not associated with overweight/obesity in both groups.
